The genera, species, and varieties of flowering plants with fibrous roots include the greater part of vegetable productions. A few of those most prized are all we need notice. Let us take first the humble *Daisy* (day's-eye), which has been cultivated from the wild *gowan* or daisy, the 'wee, modest, crimson-tipped flower,' and is now found in many varieties—the mottled crimson and white, and the pure crimson, being the more common. This plant is the hardiest of the herbaceous tribe, keeps longest in bloom of any, and may be propagated to any extent by simple separation of the roots.

Dielytra.—The Chinese Dielytra (*D. spectabilis*) is suited either to the greenhouse or open air, and is one of our best novelties. Several allied plants, including the Fumitories, are also well worthy of cultivation in the borders.

The *Primrose* family includes several pretty flowering plants. There is no great beauty in the primrose as a garden-plant, but it is useful as an early spring-flower, and succeeds the crocus in giving colour to the borders. The highest cultivated of the race is the *Polyanthus*, which sends up stems loaded at top with a bunch of flowers. The colour most admired is that shaded with a light and dark rich crimson, resembling velvet, relieved by a bright golden hue. The *Auricula* (*Primula Auricula*) is a larger plant, but varying in colour, and more delicate in many respects. It flourishes best in rich soil from old turf and rotted cow-dung. The chief colours are red, pink, crimson, purple, apple-green, and mulberry. On the petals there is a fine meal, which is injured and marked by drops of rain or artificial irrigation; and therefore flower-fanciers take care to shelter the plants with frames, and allow no drops from the watering-pot to touch them. When treated with attention, a bed of auriculas may be rendered very beautiful.

The *Campanula*, or pyramidal bell-flower, in its different varieties, blue and white, is a graceful flower, with pendent bells, which should be found in all tastefully laid out borders. It may be kept long in flower, by cutting off the blooms as soon as they begin to wither. The large herbaceous *Peony*, with its brilliant and deep crimson flower, is another choice plant; it requires little care.

Pansy.—By the French, the cultivated violet or heart's-

ease is called *pensée* (thought); hence our name pansy. No flower in the garden has lately engaged so much attention as the heart's-ease; and by means of culture and hybridising, it has attained great perfection as respects size and richness of colour. 'The most approved method of propagation is by taking off young slips in the autumn, which is the best time, as then the ground and weather are most suitable for the formation of rootlets, on account of its dampness and dulness; [but the season for striking cuttings will depend upon the time when they are wanted to flower]. A bed is prepared of light but rich soil, raised a little above the path, in order to drain off all superfluous moisture. The cuttings are then made ready, by stripping them of their under leaves, and cutting close below the bottom joint, from which the roots must spring; for if this is not done, the cutting will decay to that joint, which frequently destroys the whole. After the bed is prepared, the cuttings are arranged according to their varieties, each sort being marked by a tally-stick, numbered or named according to the pleasure of the owner. The cuttings will be found to be well rooted in about six weeks, when they may be planted out for blooming in the spring, or potted to keep over winter in a frame. The soil in which the pansy is found to flourish best is a compost of cow-dung one-half, fresh loam one-quarter part, leaf-mould one-eighth part, and coarse sand one-eighth; but peat-soil should on no account be intermixed, as it burns up the pansy completely. These ingredients should be well mingled together, and purified from worms and slugs by having lime-water frequently thrown over the heap, and in a short time it will be fit for use. The situation best adapted for the heart's-ease is one which is sheltered from the mid-day sun, but which receives a little in the morning, as it is then not so powerful as to injure the colours. Transplanting may be performed at any season, but in doing so an error is prevalent. We see the plants taken up with a ball of earth around them, and planted again with it. Now, as everything deteriorates the soil in which it grows, and as the pansy entirely pierces every particle of earth its roots can reach, therefore that which we take up with it must be entirely exhausted. When replanted, the pansy can receive very little food from its new situation, as its roots do not by nature straggle far from the stem. To prevent this starvation, it would be much better to wash away all the soil from the roots, and replant the flower with its roots unconfined; then it would be able to seek food for itself abundantly, and thereby produce much larger blossoms.'

To the amateur, the selection of suitable varieties of florists' flowers is often a matter of great consideration, and in the case of pansies, it is especially difficult; for those kinds which gain the principal prizes at flower-shows are frequently ill adapted for the usual purposes of ornament, being often shy bloomers, or defective in not shewing their flowers well above the foliage. We have therefore requested Mr Tait, a grower of the pansy who has had great experience, to give us the results of his observation, which he does in the following lists:

Varieties best adapted for general ornament in the flower-garden, being free bloomers and of good habit, shewing their flowers well above the foliage: CLASS I. *Selfs* (flowers of one colour only)—Blanche, Countess of Strathmore, Duke of Perth, Flower of the Day, Yellow Climax, Lord Dunfermline. CLASS II. *Yellow-grounds*, with margins of blue, purple, crimson, or maroon — Commander-in-chief, Cyrus, Lady Emily, Lord Raglan, Lustre, Sir J. Cathcart. CLASS III. *White or light grounds*, with margins of blue, purple, lilac, or mulberry—British Queen, Colonel Windham, Constancy, Miss Talbot, Princess.

Varieties adapted for competition: CLASS I. Jeanie, Mesmerist, Royal Albert, Sovereign. CLASS II. Admiral Napier, Alice, Duke of Norfolk, Emperor, Father Gavazzi, Monarch, Rubens. CLASS III. Countess of Rosslyn, Eugénie, Earl of Mansfield, Miriam, Nonpareil, Royal Standard, Sir Colin Campbell.

Mr Tait states, that in planting *beds* for show, he takes British Queen for white ground, with light rosy-purple margin; Miss Talbot for white ground, with dark-purple margin; Sir J. Cathcart for yellow ground, with bright reddish-crimson margin; and Lustre for yellow ground, with very dark margin. Duke of Perth is perhaps the best dark self for making a bed; Yellow Climax, the best yellow self for a bed; and Blanche the best (indeed the only really good white) self for a bed. Some of the fancy varieties are well adapted for bedding purposes.

Shrubs—Evergreens—Climbers, &c.

Among these, the *Rose* unquestionably deserves the first place, having from time immemorial been a favourite in every garden. There are some hundreds of species and varieties of roses; among which are included China-roses, hardy climbing-roses, moss-roses, Scotch roses, &c. The China-rose is delicate, with few petals in the flower, and yields a succession of blossoms through a great part of the year; it is hardy, and is green and flourishing in winter. Among red roses, the moss-rose is the most beautiful, and next it may rank the cabbage-rose; but both are excelled in fragrance by the leaves of the *sweet-brier*, a rose-shrub which, for the sake of the delicious odour of its hardy green leaves, should have a place in every garden. All kinds of rose-bushes are exhaustive of the soil, and should be frequently manured, if not transplanted to fresh mould. In order to keep them in bloom, cut off all blossoms which seem about to wither. The branches require careful pruning. For adorning the walls of summer-houses, cottages, &c., the *Honeysuckle* excels, and should, both for its beauty and fragrance, by all means have a place in every garden, however humble. The honeysuckle is a *twining* plant, and has a tendency to climb in a spiral direction from right to left, which requires to be accommodated. The *Hop* is sometimes grown in gardens, and allowed to climb on tall poles. In point of massiveness of green surface, the honeysuckle is surpassed by the *jasmine*, a tall running shrub, growing up in numerous branches, which, being well covered with small narrow leaves, is very suitable for leading up to verandahs or concealing pieces of wall. It does not adhere, and requires nailing; when carefully treated, its massive green and elegantly drooping small branches have a pleasing effect. *Ivy*, the most pertinacious of climbing-plants, will grow almost anywhere, and only requires pruning every winter or spring to keep it within bounds.

Among the various tall bushy shrubs most appropriate as an ornamental background in gardens, are the different species of azaleas, laurustine, rhododendrons, and lilacs. The *Laurustine* yields a plenteous and early supply of small variegated blossoms. The *Arbutus* is likewise a beautiful shrub, but more suitable as an embellishment in lawns; it has small greenish bell-shaped flowers, and yields a strawberry-like fruit in warm exposures. Perhaps all out-of-door exotic shrubs should yield the palm of beauty to the *Ribes sanguineum*, a plant profusely adorned with small red blossoms, which appear in spring. It resembles the common currant.

Evergreens constitute a class of shrubby plants, more suitable for the ornamental front-plots of dwelling-houses, or for approaches and lawns, than for ordinary flower-gardens; because, although the green of the leaves is pleasing in winter, when other vegetation is dead, these plants are very exhaustive of the soil; often prevent the sun from getting to the borders; and keep the ground in a litter with fallen leaves at a time when trimness is expected. Many species of evergreens are now cultivated in gentlemen's grounds; but those which

are most generally esteemed for ornamental plots or other limited situations, are the various tribes of *Laurels*, *Alaternus*, *Arborvitæ*, *Holly*, *Juniper*, and *Box*. With proper care, any of these may be lifted and transplanted into situations more agreeable to the eye, either at the beginning of September or May, when young shoots are preparing to burst forth. The plan is to dig all round them, at a distance equal to the compass of the branches, sinking the trench to a point beneath the sole of the plant; then lift them bodily with the whole mass or ball of earth round the roots. A pit must be prepared for the reception of the ball, and when placed in its new situation, fill in the rest of the pit with fine earth, laying the rootlets straight, and packing in all neatly to the surface. A copious stream of water must now be poured from a watering-pot upon the newly placed mould, round the stem; this carries the particles of earth to the rootlets, surrounding each with its proper nourishment, and giving solidity to the whole. If likely to be exposed to winds, the plant should be supported till thoroughly rooted in its new abode. (See ARBORICULTURE.)

Succession of Bloom.

The directions given in the foregoing pages, and in the floricultural calendar appended, it is hoped, will assist in leading to an arrangement whereby a constant succession of blossom may be obtained, for on this much depends. As a further aid, we offer the following hints, furnished by a correspondent to the *Gardeners' Chronicle:* 'It is the desire of every one who possesses a garden, to have as much variety of colour and succession of gaiety throughout the season as the situation and means of the possessor can accomplish; yet in viewing most gardens, even where expense is not an object, borders devoted to the cultivation of particular plants may frequently be observed to be attractive only when such plants are in blossom, and looking bare, if not unsightly, after the bloom is over. Supposing equal skill in the cultivation of plants in general to exist among gardeners, the great superiority in effect of one garden beyond another, consists in the distribution and arrangement of the plants themselves, so that a succession of blossom, and a due contrast of colour should, where practicable, keep every border furnished even to the end of autumn. In this respect, most gardens are deficient. Succession is not attended to, except for the more limited space and favoured spots near the mansion, or in front of the conservatory. In most gardens, it is considered sufficient to keep any border where plants have blossomed free from weeds and neatly raked. To the mind of the gardener, this border tells its own history, of the beauty of which he had boasted but a few weeks since; but the visitor or casual observer who walks through the garden, only seeking to please his eye with varied gaiety, makes no allowance for the past which he has not seen; and remarks, that though some parts are beautiful, a great portion of the ground has nothing worth looking at.

'By the subjoined method, the comparative gaiety of the scene may be kept up, and a relief to the eye, not without interest to the observer, preserved. Mix the seeds of the following well-known annuals:

Mignonette,	Heart's-case,
Carnation poppy,	Clarkia pulchella,
Papaver amœnum,	" alba.
Dwarf Dutch poppy,	Godetia of all sorts,
French poppy,	Antirrhinum majus,
Branching larkspur,	" sparteum,
Eschocholtzia Californica,	" versicolor.
" crocea,	Collinsia bicolor,
Campanula speculum,	Coreopsis tinctoria,
Candytuft, varieties,	Convolvulus minor,
Nasturtium,	Gilia tricolor, and other species.
Centaurea Cyanus, various.	

Then let this mixture of seed be very thinly scattered upon the borders early in the spring; it need not interfere with any ordinary work on the borders that may be required afterwards, and in places where the ground may be disturbed, many of the seeds will only appear at a subsequent period, and consequently flower later in the autumn. Most of these annuals will continue flowering until the frost kills them, and if not removed too soon, will leave behind them sufficient seed for years to come. Every gardener has remarked the strength, the beauty, and the effect of single plants of self-sown annuals that spring up occasionally in a flower-border, and have escaped that destruction which the merciless hoe, in the hand of the undiscriminating labourer, inevitably entails upon them; yet, if the intelligent labourer is properly instructed, he will soon learn to confine his extermination to weeds, and his skilful eye will spare the annuals at proper intervals.

'One case yet remains of much consequence to present as well as to future effect, though generally but little attended to: this is the frequent examination of all annuals as they expand their first flowers, and the pulling them up, unless in habit, form, and colour they are fit to remain for stock. Crowded as annuals generally are in the patches sown in gardens, their true character and beauty are seldom seen; and if among the mass sown, some few blossoms appear more striking than the rest, and the seed of these is considered more worthy of preservation, it is generally too late to take away the worthless without destroying the plants most desired; and the seed so saved from the most select variety is but little better than that from any of the other plants.

'The system now recommended gives the advantage of separation and a power of selection, with the certainty that a selected plant will, by its position as a single plant, not only blossom in beauty and vigour, but afford that abundant harvest of good seed which will amply repay in future years the trifling care thus proposed to be bestowed upon it.'

PLANTS FOR THE GREENHOUSE, AND FOR WINDOWS, ETC.

These are of various kinds, both herbaceous and shrubby, and require to be distinguished from the preceding, because they are exotics, too delicate for open-air exposure in all weathers, and require to be kept in a temperature above the freezing-point. This is done by placing them in a conservatory or greenhouse, which is a light fabric, covered with glazed frames, and, if necessary, heated a slight degree in winter by means of flues or pipes of hot water. The most approved situation of a greenhouse, of the old lean-to form, is against a wall with a southern exposure; and, if possible, placed in connection with a range of artificial vineries or hot-houses. In many instances, a conservatory is connected in a very agreeable way with the parlour of a dwelling-house, by which its beauties are enjoyed without the trouble of going out in bad weather or during the inclemency of winter. All the plants are in pots; and whenever it can be done without risk of injury, the sashes are opened, and free exposure permitted. At the country-seats of various English noblemen, as well as in public gardens, such as those at Kew and Edinburgh, conservatories are formed on a magnificent scale, so as to allow the free growth of even tall trees, such as the palm and other large tropical plants.

The most beautiful greenhouse flowers usually cultivated are camellias, geraniums, fuchsias, orchids, cacti, and azaleas. The camellia, or *Camellia Japonica*, is a woody shrub, yielding splendid rose-like flowers of colours varying from white to red. The geranium is a well-known herbaceous exotic, with clustering bunches of flowers of different colours. The fuchsia, introduced from Chili, is a handsome shrub, of different varieties, yielding exceedingly beautiful flowers, of a bright crimson hue; and the manner in which these flowers depend from the branches, like drops of ladies' ear-rings, has a singularly graceful effect. The cacti are

interesting exotics, distinguishable by their thick and succulent leaves, on which usually grow small and sharp prickles; the flowers are splendid. Besides these, we may enumerate, either for their great beauty of blossom or fragrant odours, the nerium, jasmine, gardenia, daphné, heliotrope, acacia, mimosa, eucalyptus, passion-flower, amaryllis, and calceolaria—the last very beautiful, and suitable for open air in summer.

An airy parlour or drawing-room, with windows facing the sun, may be considered a domestic green-house; and such apartments may be furnished with flowering plants, which will bloom and thrive if certain precautions be adopted.

The cultivation of plants in rooms and on balconies and window-sills, is indeed so prevalent a taste that it should not be passed over in a treatise of this kind. It is, moreover, a department of gardening in which very few succeed; nor is a great amount of success attainable. The conditions upon which vegetation depends are—heat, light, and moisture. Wherever *one* of these is wanting, we have an absence or paucity of vegetation. In the equatorial zone, for example, we have heat and light in abundance, and consequent luxuriance of vegetation wherever the soil and air are moist; but in sandy deserts, where moisture is absent, it is seen that no amount of heat or light can make up for it, for there we have barrenness. In like manner, there is in the arctic regions an abundance of moisture, but heat is there absent, and the vegetation is consequently scanty. In subterranean caverns and mines, we have abundance both of heat and moisture, but the absence of light checks the production of plants. These conditions of heat, light, and moisture are equally applicable to the growth of plants on the small scale. But as in nature, we find many peculiar plants so constituted as to resist special conditions of climate, we may materially simplify our arrangements in cultivation by selecting such plants as are best adapted for those conditions to which our domestic flowers are necessarily subjected.

Our sitting-rooms are inimical to vegetation, not so much on account of the impurity of the atmosphere, or its admixture with gases poisonous to vegetation, as from the extreme dryness of the air, caused partly by the want of those terrestrial exhalations which preserve the atmosphere near the soil in a state of humidity, but chiefly arising from the drying effects of fires and stoves in rooms. We have therefore an absence of one of the elements above alluded to as essential to vegetation—namely, moisture; and no amount of moisture, however excessive, that may be applied to the *soil* will counteract the want of moisture in the atmosphere. The plants which are found to succeed best in the ordinary dry atmosphere of rooms, with least trouble, are the cacti and other fleshy plants that are enabled, by their peculiar structure, to withstand the effects of drought. In addition to these, however, many strong growing plants succeed well with little trouble; such as the hardier sorts of fuchsias, and many of the original species of pelargonium (or geranium), especially such as have scented leaves. The improved varieties of pelargonium, and, in fact, most of the improved races of 'florists' flowers,' are too delicate for domestic culture. Many plants that require a great amount of root-moisture grow luxuriantly in rooms, such as the hydrangea and lily of the Nile. The latter is admirably adapted for a balcony or staircase, being very hardy, and having an imposing appearance, even when not in flower. Mignonette grows well in boxes of earth placed on the window-sill.

The HYACINTH (*Hyacinthus orientalis*) is one of those plants of accommodating nature and hardy constitution, which can adapt themselves to a great change of circumstances, and are thus suitable for domestic gardening. It can be grown in the closest room in the most dense part of a city, without a ray of sunlight, and without a particle of soil; in fact, the neatest and cleanest, and most successful mode of managing these plants, is to place them in glasses of water, from which their roots derive all the materials requisite for healthy growth. It requires great skill, however, to produce in this country the finest flowers of which the hyacinth is capable; and on account of its rapid deterioration in our climate, our florists obtain a yearly supply of bulbs from Holland. The famous nursery-gardens which supply the greater part of Europe with hyacinth bulbs, form quite a feature of Haarlem, occupying the southern suburb of the town.

The common form of hyacinth-glass is well known; there are, indeed, various kinds in which hyacinths grow well; and the form of glass is chiefly a matter of taste and convenience, the great point being to allow plenty of room for the roots: some of the best hyacinths we have had were grown in those narrow cylindrical jars used for preserving anatomical preparations, the bulb merely resting on the top without any cavity for its protection, as in the usual form of hyacinth-glass.

The common hyacinth-glass is beginning to give way to an improved form, called Tye's Registered Hyacinth-glass, which has recently been brought into notice in Scotland by Mr C. Alexander. This glass is shewn in

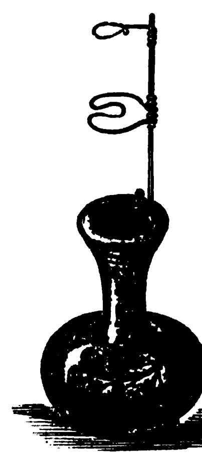

Fig. 4.—Hyacinth-glass.

the accompanying wood-cut, and is manufactured of many elegant patterns. It will be seen that provision is made for supporting the flower-stalk, which is naturally inclined to one side.

The first step in cultivation may be said to be the choice of bulbs. These should be selected as early as possible, an arrangement which will not only insure to the purchaser an extensive choice, whereby good bulbs may be secured, but they will be found to be in better condition than at a later period. In any case, they should be procured before any evidence of growth is visible, otherwise the bulb will become weakened from its tissues giving off their stores of nourishment to the central shoot of leaves. Inexperienced growers are apt to choose those bulbs that have already begun to grow, which it will be seen is a bad practice.

The bulbs should be set in glasses in the month of October, the glasses being filled with water to within an eighth of an inch from the base of the bulb. If placed in the dark for a week or two after planting, the production of root-fibres will be facilitated; but a damp situation is very injurious. After the roots are somewhat advanced, the shoots develop; and during their progress, light and air should be given freely, the plants being placed as near the window as possible. They will succeed well enough, however, on a table or mantel-piece beyond the reach of the sun's direct rays; but in a room

where a strong fire is kept, they should not be much exposed to its drying heat. Some growers recommend a small quantity of salt to be added to the water, but it is doubtful whether this has any beneficial effect. Mr Tye observes: A variety of methods for giving vigour to the plants, and brightening the colours of the flowers, have been resorted to—such, for example, as adding to the water a few lumps of charcoal, a little nitrate of soda, or a small portion of saltpetre; but the following has been found to answer well: Dissolve half an ounce of guano, with so much chloride of lime as would equal the size of a large pea, in a quart of rain-water. Let this mixture stand for a day or two to become clear. Pour about two tea-spoonfuls into the bottle twice a week, after the flower appears well out of the bulb.

The water should be changed regularly once a week from the time of planting to the time of flowering. Soon after planting, it will be found that a quantity of decaying vegetable matter becomes partially detached from the basal portion of the bulb, inside the circle of root-fibres; this should be carefully removed by repeated washings, taking care not to injure the root-fibres, for if broken, they will not be reproduced, as in those plants that have branched roots. When side-shoots appear from the bulbs, they should be pinched off, as they draw away the nourishment from the flowers; but where two trusses of flowers appear, they should both be allowed to expand. When the flowers begin to open, the hyacinths should be placed on a table out of the sun's reach, or otherwise protected from its rays, and in as cool a situation as possible, which will prolong their period of bloom.

There are numerous varieties of hyacinths in cultivation, more than 2000 being enumerated in catalogues; of all shades of blue, red, white, and pale-yellow—single and double.

Several species of fungi are apt to grow in the water and on the bulbs, and are only to be got rid of by careful washing and repeated changes of water.

On the subject of the cultivation of flowers in windows, we find the following useful observations in the *Gardeners' Chronicle:* 'The three principal things requiring consideration are *air*, *light*, and *moisture*. Plants kept in windows naturally extend their branches and leaves to the light, and they thereby become one-sided; and it is wrong to endeavour to make them otherwise by frequently turning them, as the plants will as constantly turn their growth to follow the light, which not only weakens them, but spoils their appearance. As for plants receiving no perpendicular light, it is more natural to spread them out, forming one good face or tier of healthy foliage to the window; for well-balanced heads under such circumstances are almost out of the question. Place them as near the glass as possible; of course windows having a south aspect possess the greatest advantage.

'Judicious watering of plants in rooms is perhaps the most important feature in their management; and it is unfortunately in most cases ill understood, being too often given mechanically, as it were at stated times, whether required by the plants or not; and by a too eager desire for their welfare, they are frequently surfeited to death with water, which is justly termed "killing by kindness," and is practised with success, especially by ladies, from a false apprehension of their wants. In summer, this cannot be easily accomplished, unless the plants are allowed to stand in saucers constantly filled with water, which, by overloading them with juices, will soon engender sickly soft growths, unsuited for the production of flowers or healthy foliage. An exception to this rule is the growth of annuals in pots during summer: they, if well drained, may stand in feeders; but these, whenever used, should be half-filled with fine gravel or sand, which may be kept in any state of moisture. The best and only general rules that can be adopted are—in *winter*, keep plants, not then growing fast, rather dry; in *spring*, increase the quantity with their activity and the sun's power, keeping them in a medium state of moisture; in *summer*, water daily; and in *autumn*, decrease with the length of day, and the returning torpidity of the plants, until the dry state of winter is again reached. All this resolves in the following: Plants, when growing fast, may have free supplies of water, which must be lessened as their growth approaches maturity, and cease, or nearly so, when that is attained, until the return of their growing-season. As regards *air*, similar rules to those given for watering may be followed; and indeed they are analogous. In *winter*, when the plants are not growing, large supplies of air are not so important, enough being usually given by the room-door. As *spring* advances, increase the quantity, carefully guarding against the cold of mornings and evenings, or cutting winds; and if the plants are placed out in the middle of fine days, take care to bring them in before the chill of evening comes on. After the first or second week in May, they may be set outside for the summer; and towards the end of September, or as soon as heavy cold rains occur, they should be placed again in their quarters for the winter, setting them out of doors when fine, or supplying them with plenty of air by the window, until the cold weather and decrease of moisture at the roots bring them to a state of comparative rest. It should be remembered in spring and autumn, that the plants must not go out to-day because they were placed out yesterday, but the weather alone must determine; sudden changes must at all times be avoided. The leaves of plants act as lungs, by which they breathe; if they become dirty, their respiration is impeded; therefore an occasional careful sponging will be useful to them. In spring and summer, allow them the full benefit of genial showers, which will do them more good than any artificial watering. Never use spring-water if soft or rain water can be had; and always let it be about the same temperature as the air in which the plants are growing. It is hardly necessary to mention the removal of decaying leaves and flowers; the last are exhausting as well as unsightly.

'One principal potting is usually required, and afterwards as often as the plants may fill their pots with roots, or seem to require it. The most important thing is good soil, which, if composed of three parts loam, of a fibrous open texture, with a fourth of dung, most plants will thrive in, using plenty of drainage to allow water to pass off readily. Never suffer the surface-soil in the pots to become hard or moss-grown, but let it be loosened occasionally with a piece of stick.

'Succulents are well suited for growing in rooms, as they are not so impatient of either air or water as most other plants; and the abundance of their beautiful flowers renders them objects of interest. Cactus speciosus, Jenkinsonii, flagelliformis and speciosissimus, mesembryanthemums, and flowering aloes, deserve especial notice.'

All that is necessary for successful indoor culture, is attention to the general directions given above. If plants have sufficient air, light, warmth, and moisture, and be potted in proper soil, nothing else is needed, save a little care in keeping them clean, occasionally stirring the upper portion of the soil, turning them regularly to the light, lopping off old wood, pruning unseemly shoots, and removing decayed leaves. It may sometimes happen, notwithstanding all ordinary care, that a few, such as the pelargoniums, may be infested with small green insects, or may otherwise take disease and languish. The former are generally destroyed by a sprinkling of powdered lime, the fumes from a tobacco-pipe, or even, where the nature of the plant will admit, by a thorough drenching with pure water.

Another direction to be borne in mind is, never transfer a plant from one situation to another of a widely different character, without some previous preparation. Vegetables no doubt possess wonderful powers

of accommodation, but there is a limit to this principle; and a plant reared in the hothouse will no more endure the sudden exposure of open air, than the animals of India could live and propagate in Iceland. Thus many of our rarest exotics are permanently injured by *sudden* removal from the stove to the open stand, or from the open air and conservatory to the drawing-room. Plants intended for transferences of this kind should either be taken at the period of their repose, or immediately before their breaking into blossom, if their flowers be the object in view.

Pots and Stands.

Since the main object of domestic floriculture is to improve the taste for what is lovely and ornamental, it should be the aim of all growers who can afford the outlay, to procure pots of as handsome shapes as possible. The common earthenware pot is often very clumsily made, though not of itself an inelegant object; but others may be constructed with ornamental mouldings in relief, or in the form of vases, urns, and the like, which add greatly to the grace of a flower-stand. Pots may also be constructed of stone, of polished slate, as recently manufactured by Mr Beck of London, of cast iron, wood, and the like, and in highly elegant fashions, either to be set on plain shelving or on ornamental stands. Elegance, however, does not consist in exuberance of ornament, and correct taste will avoid all grotesque and fantastic shapes. There is an endless variety of pots; some intended to afford better drainage than the common sort; others whose main object is display and ornament. Whatever be their form, gardeners distinguish them by numbers, thus: The smallest ones are called *thumb-pots;* the next, *sixties,* which are 3½ inches deep, and 3½ inches wide at top; *forty-eights* are 4½ inches deep, and 4½ inches wide at top; *thirty-twos* are 5½ inches deep, and 5½ inches wide at top; *twenty-fours,* 6½ inches deep, and 6½ inches wide at top; *sixteens* are 8 inches deep, and 7½ inches wide at top; *twelves* are 8½ inches deep, and 8½ inches wide at top; *eights* are 9 inches deep, and 9 inches wide at top; *sixes* are 10 inches deep, and 10 inches wide at top; *fours,* 11 inches deep, and 11 inches wide at top; *twos,* 12 inches deep, and 12 inches wide at top—all inside measure. The actual sizes vary, however, with different manufacturers.

Fig. 5.

Stands are commonly made of wood or cast iron; but we have also seen very cheap and pretty ones constructed of a wooden upright, with suspension arms of stout iron wire. Wooden ones, with plain shelving, of circular, or semicircular, or quadrantal forms, make very handsome stands for recesses and corners; those on single uprights, with branches for the support of the pots, are usually constructed of iron wire, or of cast iron painted, and are best adapted for central situations in lobbies and drawing-rooms. It may not, however, be in the power of some to procure flower-stands of either description; and for such, one board placed in the window-recess, so as to bring merely the top of the first row of pots within influence of the light, and a second level with the top of the first pane, will make no inelegant display; the effect of which will be heightened by suspending some light pots from the lintel above, containing such hanging-plants as that called Humility (*Linaria Cymbalaria*). Pendent plants, in fact, form very handsome appendages to a dwelling-apartment, and no amateur should be without some to grace his collection. Of these may be mentioned, as worthy of adoption, Saxifraga sarmentosa, Kangaroo vine, epiphyllous Cacti, ferns, lycopodiums, &c.; and, with a little management, the prostrate verbenas, lobelias, and mimuluses, the trailing mesembryanthemums, with Campanula rupestris, fragilis, hirsuta, and a multitude of plants which resemble them in their habits. Even some annuals, flowered in early spring, as Nemophila maculata and insignis, create a good display when suspended in pots; and many of the tender creepers hereafter mentioned may be trained pendent as well as erect. It must be kept in view, however, that the atmosphere of a room is *usually* too dry for such plants.

Ward's Cases.

It may happen, from the vitiation of the air in towns, and in dwelling-apartments, or from other circumstances, that it is impossible to grow the plants we most wish in open pots. To remedy this, a plan was many years ago devised by Mr Ward, a surgeon in London, of keeping the plants under close glazed frames, in which situation they grow and flourish in perfection. These frames are generally known by the name of Ward's Cases, and may be seen in almost every large town, constructed of every shape and size, according to the taste or means of the grower. By aid of these, any one, whether inhabiting the most humble or the most splendid dwelling, provided it be freely exposed to the sun's light, has it in his power to cultivate a miscellaneous collection of plants, at an expense so trifling, as to be within the reach of the most moderate circumstances. One of these cases, of a very complete structure, is represented, with its collection of plants, in the following figure. On the stand or table is a strong box, lined with zinc or lead, and filled with well-moistened loamy soil, underlaid by a thin subsoil of turfy loam, and this resting on a porous

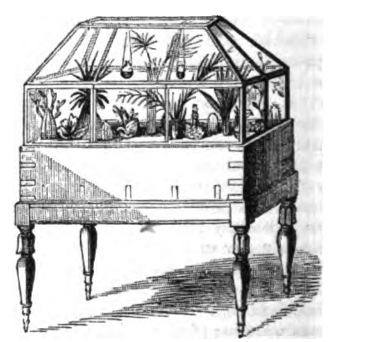

Fig. 6.

stratum of gravel, or broken earthenware. This composition is meant to represent a natural fertile soil, which it does to perfection, the water lodging among the gravel till the wants of the plant in the superior mould require it. Over this box is placed a close-fitting glass cover, which completes the apparatus. The lighter and thinner the glass-frame, and the finer the glass, the better are the plants exposed to view, and the more readily do they receive the sun's light. This plot of soil, with its glazed framework above, forms a little world of itself, in which the plants grow and flourish. When the moisture of the soil within is vaporised by the heat of the sun, it collects on the inside of the glass, and trickles down again, so that the plants are never subjected to irregular or capricious watering. The case is not absolutely air-tight; if it preserves a certain regular amount of moisture and warmth, while it excludes

dust, soot, smoke, and other noxious fumes, it does all that is required. The Ward's Case may be large enough only to cover a single plant, or to become a domestic conservatory.

Cases of the kind described may be used either for indoor or open culture, and answer as well for a little front-plot or back-court as for a drawing-room. They can be also conveniently put up in balconies, or even over the entire window, so that the panes may serve for one side of the conservatory. Many such are now to be seen in our large towns, even in the smokiest and least inviting quarters. This sort of double window, if we may so speak, is admirably adapted for tall plants and flowering shrubs, or for suspending pots, and is altogether a very pretty annexation to a dwelling. Lofty and partially close cases of this sort are fitted for almost every species of greenhouse plant; natives of damp and shady situations, grow and bloom in them to perfection; but the moistened and shaded atmosphere of a small and closely fitted case is destructive to many flowering-plants. Among those most suited for Ward's Cases are many lovely and rare plants, which will amply repay the attention of the case-grower; such as ferns, lycopodiums, and mosses.

Rare exotics need not, however, be sought after. 'The plants to furnish it,' says Mr Ward—who, however, uses cases of *large* size—'can be procured abundantly in the woods in the neighbourhood of London. Of these I will mention a few. The common ivy grows most beautifully, and can be trained over any part of the case, agreeably to the pleasure of the owner. The primroses, in early spring, will abundantly repay the labour of fetching them, continuing for seven or eight weeks in succession to flower as sweetly as in their native woods. So likewise does the wood-sorrel, the anemone, the honeysuckle, and a host of other plants, independently of numerous species of mosses and of ferns. Some of these latter are more valuable than others, in consequence of the longer duration of their fronds, such as *Lastræa dilatata*, and its numerous varieties. There are likewise many cultivated plants procurable at little or no cost, which grow without the slightest trouble; such as the *Lycopodium denticulatum*, the common musk-plant, myrtles, jasmines, &c. All the vacant spaces in the case may be employed in raising small salads, radishes, &c.; and I think that a man would be a bad manager who could not, in the course of a twelvemonth, pay for his case out of its proceeds. These remarks apply chiefly to situations where there is but little solar light. Where there is more sun, a greater number and variety of flowering plants will be found to thrive; such as several kinds of roses, passion-flowers, geraniums, &c., with numerous beautiful annuals—namely, *Ipomœa coccinea*, the species of *Nemophila*, *Convolvulus*, and a host of others: the vegetation, in fact, can be diversified in an endless degree, not only in proportion to the different degrees of light and heat, but likewise by varying the quantity of moisture; thus, with precisely the same aspect, ferns and bog-plants might be grown in one case, and aloes, cactuses, mesembryanthemums, and other succulent plants in another.'

Case-grown plants, after the first preparation, require little or no care; the case need only be opened for the removal of dead leaves, or for a little trimming when required. Plants in open flower-pots are exposed to the vicissitudes of change of climate, and require constant watering; but the plants in these cases seem to be independent of any change of temperature in the air, and water themselves. The moisture rises by the sun's influence from the moistened earth, refreshes the leaves of the plants in its aërial condition, and during the cool of night, falls to the earth again like rain or dew. In this manner there is a constant succession of rising and falling of moisture, in imitation of the great processes of nature daily going on in the fields around us.

Walls and Trellises.

Where it is objectionable to fasten climbing-plants to walls, a light trellis-work of wood or iron wire may be employed; permanently fixed where the climbers are perennial, but movable where they are grown merely for summer purposes. By being removed in autumn, and kept dry, a wooden trellis, originally of small cost, will last for a number of years; while its removal, along with the withered branches of the plant, is a positive improvement to the appearance of the dwelling. Nettings of string or wire make very convenient leaders when other material cannot be had; and these may be woven along the outside of doors and windows, where other frameworks might not be permitted.

Among the *hardy* species adapted for trellis-work and walls are the honeysuckle, the ivy, many varieties of the rose, the jasmine, the small white clematis, the Pyrus Japonica, Lathyrus, or even the hop, where an easily nurtured and quick-growing climber is wanted. For summer purposes merely, a selection from the following genera may be made: Cobæa, several species; Convolvulus; Lathyrus, several; Lophospermum, several; Maurandya Barclayana; Tropæolum, several; Passiflora cærulea.

It has been often remarked that, of all flowering plants, climbers present the most graceful forms which can be contemplated under the open sky; but true as this may be, the tender varieties are not the less graceful when cultivated in the greenhouse. Grown in pots, and sustained by appropriate frameworks, they can be trained to almost any shape, be it urn, vase, obelisk, or pillar—a screen of living net-work, or a fairy arbour. Trellises affixed to the outside of pots can be had of a thousand designs, and they may be constructed of wicker, slender painted rods, cord, or copper wire, which is one of the most pliable and durable of materials. By the adoption of this plan, with frequent prunings, climbers may be made to clothe a trellis not more than a few feet high, and so requiring no larger space than a small shrub, flowering profusely. Climbers are usually not of difficult culture, for we have seen a cottager's window shaded within by a screen-work of leaves and blossoms, more effectually than it could have been by the costliest Venetians.

Rock-work and Aquariums.

If space and means permit, a flower-garden may be much improved by introducing a piece of artificial rock-work and a small pond; because, in connection with these, certain highly interesting plants may be reared, which would not answer on a plain surface. In order to increase the effect, the pond should be at the base of the rock-work, and receive from it the trickling of water which has been conveyed to the summit in pipes. Let the rock-work have a natural appearance, with rugged sides, and perhaps be ten or twelve feet high. Rocks of the same kind and colour should be placed together. A dark cave, penetrating into the thickest part of the erection, is not very difficult to construct; and when encircled with ivy, it will form an interesting object. Rock-plants of every description should be profusely stuck around, and in twelve months the whole scene will exhibit an impress of antiquity far beyond anticipation. The undertaking, when completed, will present a field of varied and interesting study, and more than compensate for all the attention and outlay bestowed upon it. The aquatic and rock plants, which formerly were 'far to seek and ill to find,' will thus be brought within the range of everyday observation. If the situation is secluded and in the country, the wagtail, oxeye, and stonechatter, may be attracted to the spot, not perhaps because they are lovers of the picturesque, but because they find everything here suited to their nature; and

colonies of the wild-bee will soon be seen and heard around the interstices of the rocks. A weeping-willow adjoining one or two mountain-ashes, and some of the hardy varieties of fuchsias mirrored in the lake, will add materially to the beauty of the scene; and if the spot be airy, there might, with advantage, be planted, on the top of an eminence, the *Scottish thistle.*

Among the plants suitable for growing from the crevices of the rocks may be mentioned various heaths and mosses, the Valeriana dioica, Trifolium alpestre, Thymus Chamædrys, Epilobium alpinum. Many plants might be mentioned as suitable for the marshy borders of the pond, as the Acorus, Littorella, Lychnis floscuculi, Saxifrages, Primula farinosa. We should recommend the unprofessional gardener, in replenishing either a rock-work or pond with appropriate plants, to consult a nurseryman skilled in the subject, as soil, air, climate, moisture, and other circumstances require careful consideration. The great drawback of rock-works is, that in many situations they become harbours for snails, wood-lice, and other vermin injurious to gardens.

Of late years, the attention of cultivators has been drawn to the water-lilies—those lovely Naiads that adorn the lakes and rivers with their ample foliage, and, raising their gorgeous flowers with the morning sun, recline them

'In graceful attitudes to rest,'

as the god of day sinks in the western horizon. The use of these plants in outdoor landscape-gardening—especially in lake-scenery, for which their expansive foliage and showy flowers render them so well adapted—has arisen chiefly from the attention recently attracted by the gigantic Victoria regia, the Royal Water-lily of South America, whose botanical peculiarities have been already referred to in this work (SYSTEMATIC BOTANY, p. 90). This magnificent plant, with its gigantic leaves, eighteen feet or more in circumference, and delicate rose-coloured flowers thirty-six inches round, is represented in the frontispiece. Being an aquatic of such huge proportions, it requires for its successful cultivation a special structure, with a large central tank of water; but this may be made available for the culture of other aquatics, and the Victoria regia has thus led to the extended culture of exotic aquatic plants. Many new kinds of these have been recently introduced, especially species of *Nymphæa*, among which there is indeed great variety of colour and form, from the little *Nymphæa pumila* to the huge *N. gigantea.*

Some beautiful designs have been published, shewing the applicability of aquatic-gardening to the imitation under glass of tropical scenery; but we prefer representing here a simple diagram (vertical section) of a

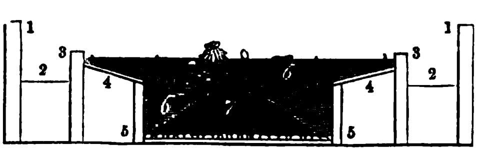

Fig. 7.

1. Outer wall of the building; 2. Foot-path; 3. Outer wall of the tank; 4. Bank of soil; 5. Inner wall of the tank; 6. Water; 7. Mound of soil in which the plants are rooted.

tank for exotic or hardy aquatics, believing that any one can readily adapt it to the size and circumstances of his garden, and render it picturesque according to the means at disposal.

The Parlour Aquarium.

The parlour aquarium or vivarium forms an interesting companion to the Ward's Case; it has for its object the cultivation of aquatic or water plants. It may, in fact, be described as a combination of the Ward's Case and the gold-fish globe; one object being, in addition to the cultivation of plants, the illustration of the mutual dependence of animal and vegetable life. The parlour aquarium consists usually of a water-tight box with glass sides, which may be of various forms, and of size corresponding with the object of the cultivator. The bottom of the box is lined with soil and picturesque fragments of rock, amid which are planted various aquatics, such as Vallisneria spiralis (fig. 8), Anacharis

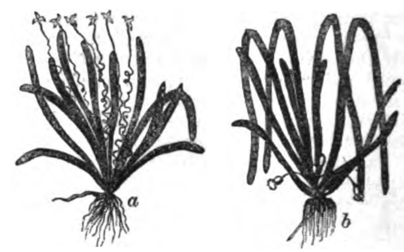

Fig. 8.—Vallisneria spiralis.—*a*, female plant; *b*, male plant.

Alsinastrum, species of Callitriche, and other neat aquatic plants. Aponogeton distachyon, although usually a large and unwieldy plant, is admirably adapted for such cases, when carefully grown for the purpose, as is evidenced by a plant now before us, which was originally raised from a seed in a common gold-fish globe, and within such circumscribed limits continued to produce a periodical supply of its beautiful white flowers, while under the care of a lady who is now botanising among the hills of Northern India. In addition to the plants, gold-fishes, sticklebacks, and other small fishes, may be introduced—even the lamprey, perch, and pike, if the aquarium be large enough; together with fresh-water mollusca—such as species of Cyclas, Planorbis, Limneus, and Physa. The mollusca multiply to a great extent, affording food for the fishes. The plants consume the carbonic acid produced by the animals, appropriating the carbon, and setting free the oxygen in a gaseous state, again to support animal life. It is a great mistake

Fig. 9.

to suppose that a large vessel is required. We have already mentioned incidentally that aquatic plants may be grown well in an ordinary fish-globe; and the above wood-cut represents a simple form of

aquarium which the writer of these remarks has employed successfully for many years—which was in use, in fact, as a miniature botanico-zoological garden long before such things became known to the world under the names of 'aquarium' and 'vivarium.' A glass of the kind here represented, measuring about eight inches across, affords ample accommodation for water-plants, such as Callitriche, Vallisneria, Anacharis, minute Algæ, &c., with mollusca, hydras, cyclops, and other small animal forms; and extensive experience and observation have taught us that a series of vases of this kind will be found more useful by the *microscopical* observer than an aquarium of larger size. Where, however, it is the object to study the habits of fishes and the larger plants, an aquarium of several feet in length, and corresponding depth of water, must be obtained.

Even more interesting than the ordinary aquarium is the marine vivarium, in which are introduced, in *sea-water*, the beautiful red and green sea-weeds, corallines, fishes, marine mollusks, nudibranchs—those graceful *ferns* of the animal kingdom—star-fishes, sea-mice, sea-anemones of varied form and hue, and all the other exquisite forms of life that swarm in old Ocean's caves. In the case of marine productions, it is found much more difficult to preserve the water sweet, and therefore it must be frequently changed or aërated, by being passed through the rose of a watering-pot. In forming the vivarium, sea-weeds must be removed, attached to a portion of their native rock. Where animals have to be taken to a great distance, they are frequently more safely conveyed in moist sea-weed than in sea-water itself. In March 1856, we spent a pleasant afternoon on the shores of the Isle of Wight, and got some prizes in the way of nudibranchiate Mollusca; these were hastily placed in a botanical vasculum among some sea-weed. We crossed to Portsmouth, took the night-mail to London, arrived at Waterloo Bridge at four in the morning, took a peep at the smouldering ruins of Covent Garden Theatre, left our card at Bedford Square for a friend with whom we had promised to dine on our way north, took train at Euston Square at six, and finally reached Edinburgh at ten o'clock the same night. We opened our box, and the nudibranchs were all alive!—those fragile things, that the merest touch of a finger seemed sufficient to destroy. They were placed in our vivarium, and thus had we the pleasure of examining their beautiful forms, and studying their habits, as well as if the Isle of Wight, with its fertile shores, had been brought into the Firth of Forth.

GARDEN-PLOTS IN TOWNS.

The attempt to have a neat and flourishing garden or garden-plot in populous towns is very often defeated by the abundance of smoke and other impurities in the atmosphere; for, as repeatedly mentioned, pure air is essential to the proper growth of plants. It is found, however, from experience, that certain kinds of shrubs and flowering herbs are less delicate in this respect than others; and that, with a reasonable degree of care, open plots in towns may be made to yield a surface of vegetable bloom and beauty. On this branch of flower-culture, so important to many town-residents, there appeared some time ago a well-written paper in *The Magazine of Domestic Economy*, describing the experience of an amateur florist. We take the liberty of extracting from it the following passages: 'When I first took possession of my garden [in town], I found it encumbered with old lilacs and laburnums, the common aster, and other ordinary plants. These I immediately removed: by my west wall I planted a Buddlea globosa and a Virginian creeper; and by my south wall, which was partly covered by a vine, I planted the Jasminum revolutum, the small white clematis, and the Pyrus Japonica. The last grew luxuriantly, and bore an abundance of flowers, which, glowing upon the light wall, enlivened my prospect in winter. I had much of the south sun in my garden, but none of his morning beams reached it, and there was a corner which never had a gleam at all. In this spot I planted a quantity of roots of the lily of the valley, and they flowered well, although late. The laurustine also grew well with me; and I should strongly recommend this pretty shrub, together with the laurel, instead of those deciduous shrubs which we see in town-gardens. The latter become very shabby as they grow old; neither the lilac nor syringa flower well in confined situations; besides this, the untidy appearance of their falling leaves is a great annoyance. My jasmine grew quickly, and, with the clematis, soon covered as much wall as I could afford to them; the great inconvenience of the latter plant is, that it requires frequent attention as to nailing up, and this, where there is not a gardener always at hand, is troublesome; as, although the stem should be cut down within three feet of the ground every autumn, yet the young shoots soon grow beyond a woman's reach. However, it is worth while putting ourselves to a little trouble for the sake of the delicious scent of the flowers of this pretty trailing-plant. As regards perennials, I daresay all who are fond of flowers have endeavoured to nurse the China-rose, and induce it to flower in the town. I have grieved over many a healthy plant which refused to shew a single bud, and watched the gradual wasting away of others, notwithstanding my unceasing care. The common Provence roses, both white and red, flower well in the town; but it is vain to attempt the China—it requires a very pure air; and I do not know any flower whose colour varies so much with the quality of the atmosphere. I am but slightly acquainted with the names given by botanists to the numerous varieties of roses; but I have tried many of them, and found the Tuscan, the rose de Meaux, the Tudor, the little early crimson, and one surpassing them all in beauty, the Bengal celestial (I believe), flower extremely well.

'With regard to spring-flowers, the snow-drop I could not tolerate in the city—the smoke robbed it of all its beauty; the crocus, either the mice or the sparrows would not leave undisturbed; and after replenishing the edge of my border several times, I gave up the matter. The hepatica and gentianella flowered well with me; anemones also I had of very good colours. Heart's-eases pined away after the first year, but they were easily replaced, and they were too ornamental to be relinquished. Then followed the white lily, and a variety of irises, all of which increased fast, and flowered abundantly. The peony I could never persuade to flower; in the first place, it does not blossom well until it has been for years settled in a garden, and I believe its beauty even then is greatly dependent upon the purity of the air. My buddlea was every spring covered with its golden balls, and grew so quickly that I scarcely knew what to do with it. I am surprised this beautiful shrub is not more common: it is perfectly hardy, even as a standard; it will remove well, even when it has attained a considerable size; it is very easily raised by layers; and there is an air of grandeur about it, both as to leaves and flowers, that raises it above the common flowering shrubs of our gardens. But we go on in the old-fashioned manner of planting our gardens. The same varieties of deciduous shrubs are taken, without considering with how much advantage their places might be supplied by those more lately introduced. The magnolia, for instance, grows quickly and flowers abundantly in the city upon a south wall; and the arbutus is not at all particular with respect to situation. The Bignonia grandiflora also does not withhold its scarlet trumpet-like blossoms in the immediate vicinity of a steam-engine. To return to my garden, the glory of which in the autumn was the Lobelia fulgens; I managed it thus: I sank in the ground up to the rim, a large and deep seed-pan; this I filled to about three-quarters of its depth with rich soil, properly

mixed, and planted my roots. As soon as the shoots appeared, I supplied them plentifully with water, and from time to time added more soil. The plants grew luxuriantly, furnishing tall and thick stems, with large and highly coloured blossoms; indeed, the gardener who had assisted me said that he had never seen finer flowers. The sweet-scented marvel of Peru thrived well with me, and the tiger-flower also. Carnations and picotees I tried one year, but was so much disappointed in the result that I gave them up, although very reluctantly, as I believe carnations do not require a very pure air; and I have fancied since that my failure with them arose from some other cause than the smoky atmosphere. Dahlias also, although they flowered very well, I gave up. The Amaryllis lutea flowered well with me when once established, and the Hemerocallis cærulea and flava did the same.'

FLORICULTURAL MONTHLY CALENDAR.

January.—Little can be done in the flower-garden except in open and dry weather; but advantage ought to be taken of favourable intervals to make the plots and borders neat. Propagate, by division of roots, daisies and thrift; protect the beds of hyacinths, anemones, ranunculuses, and tulips, by a covering of coarse litter. Top-dress auriculas, using a compost of light loam and two-year-old cow-dung, mixed with a twelfth each of sea or river sand, and rotten wood. Plant all the bulbous roots that are still out of the ground. Sow mignonette, stocks, and other half-hardy annuals, in heat, using the propagation-pot, by which means the entire number of seedlings—allowing for previous thinning-out—can be transferred, with roots undisturbed, to the plots or borders.

February.—Attend to the foregoing general directions; cut turf for lawns; fork and clean the flower-borders. Plant anemones and perennial herbaceous roots; and transfer others, dividing the crowns, to multiply the species, such as the primrose, single and double, and the polyanthus. Transplant carnations, also the divided roots of campanula, lobelia, lychnis, mullpink, and Dianthus sinensis. Sow, in mild heat, any annual flower-seeds, and auriculas and mimuli, in boxes or pans; also the beautiful Primula sinensis. Excite choice dahlia-roots, placing them in hotbed frames, or in troughs or pots of old tan, or any light moist substance, on the floor of a stove or vinery at work.

March.—Sow, under glass, tender annuals, including balsam-seed, collected from the best double flowers. Plant box-edgings; also evergreen shrubs of every description. Transplant autumn-sown annuals, and protect them till fresh-rooted; as clarkia of every kind, mignonette, schizanthus, &c.; and sow, under glass, stocks, china-aster, clarkia, dahlia, campanula, larkspur, pentstemon, amaranthus, tobacco, and all the hardy annuals. Take cuttings of hydrangea from the tops of the shoots; these, if the buds be full, sometimes will produce a fine flower-head, and the effect is striking.

April.—Plant hollyhocks, carnations, and other biennials and perennials, for flowering; at this season, every herbaceous plant is almost certain to succeed. Campanulas—the tall pyramidal—raised by cuttings in autumn, may now be transferred to pots of loam and leaf-mould; and as the plants grow, they are to be constantly shifted, till they come into pots, wherein they will bloom profusely. If placed in the borders, they require no peculiar treatment. Sow in a pot the seeds of this variety of campanula (seedlings frequently produce the finest plants; they require profuse watering); also the seeds of the pansy, to procure new varieties. Propagate, by cuttings, salvias, verbenas, rockets, and fuchsias. Bud China, noisette, and moss-roses, on dog-rose stocks. Divide the roots of dahlias, either retaining one single tuber with a sprouting eye, or twist out very cautiously a single shoot, so as to detach it from the base, planting it in the smallest pot of sand and leaf-mould; a gentle hotbed will facilitate the protrusion of roots. Sow most of the hardy annuals in the open ground.

May.—This is the season to stock the flower-garden with those plants which have been prepared during autumn, winter, and spring; and therefore transfer, from the propagation-pots, annuals raised in them, by lifting the whole mass, and depositing it in a spot prepared in the border: thus trouble and loss of time are obviated. Sow annual seeds in the open ground for succession. Plant the parterres with groups of fuchsia, calceolaria, petunia, verbena; and at the latter end, form masses of the scarlet and variegated geraniums, as well as of the stage and fancy varieties. Propagate, by cuttings, China-roses of every kind, planting them two joints deep, in a shady situation; also calceolarias of the shrubby kind, Peruvian heliotrope, &c. Propagate, by slips, lychnis, double rocket, pansies, and wall-flower; thin out the superabundant shoots of perennial asters, antirrhinums, pentstemons, phlox, and all luxuriant herbaceous plants.

June.—Propagate, as during the last month, and plant young side-shoots of hardy lobelias, in shady borders, under a hand-glass. The pipings of pinks, placed in sandy earth, are to be closely covered in the same way, till completely rooted. Greenhouse plants may now be arranged in a north aspect; the pots to stand on a deep stratum of coal-ashes. Azaleas, Acacia armata, heaths, rhododendrons, and such plants, are greatly improved by being turned out of pots, and planted with the entire balls in an open peat-border.

July.—Bud roses on wild stocks. A pretty effect is produced by inserting one or two buds of the deep-red China in the common China-rose; the different tints of the two roses are very pleasing. Propagate, by cuttings, the Chinese azaleas, half-shrubby calceolarias, linums, pelargoniums, fuchsias, myrtles, and other exotic shrubs. Layer carnations in sandy earth; peg them near the incision with hooks of fern-fronds. Sow mignonette in small pots for winter; also annual flower-seeds for bloom in September.

August.—Bud roses as before. Plant seedling herbaceous plants; repot auriculas, removing the suckers, and detach the black ends of old roots with the finger and thumb. Sow the seeds of annuals and pansies. Take cuttings of all the fine pelargoniums that are out of flower early in the month; also of calceolarias, shrubby and half-shrubby; and of antirrhinums, pentstemons, which require no heat, but should be placed in a cold frame.

September.—Plant the crocus and other early bulbs. Transplant herbaceous perennials and pinks to permanent beds, if perfectly rooted. Propagate, by cuttings, China-roses in the open borders; also petunias, heliotrope, salvias, geraniums, calceolarias, &c.; they require only a hand-glass and light soil, or slight bottom-heat. Sow auricula seeds in pans in the greenhouse; also clarkia, collinsia, and other annuals, to be preserved in pots all winter. If the pyramidal campanula be out of flower, take up one of the finest roots; break it to pieces, and half-filling a large pot with loam, place the pieces on the earth, fill the pot with loam, and keep it merely protected from frost all winter. Raise every geranium or other greenhouse plant now in open ground, and repot in soil suitable to each. Cut back to low buds the scarlet and other geraniums, and place all the plants under glass, to recover from the removal; make cuttings of the best amputated shoots of geranium. Gradually diminish the watering of all greenhouse plants.

October.—Plant, towards the end of the month, bulbs of the hyacinth, narcissus, and tulip, the common jonquil, and daffodil, and common anemone roots, &c.; also shrubs of every description, though evergreens generally succeed in spring. Hyacinths in pots, filled with a compost of light loam, sand, and vegetable earth, should be plunged to the rims in ashes, or light earth, under the glass of a cold frame; and when the plants begin to grow, the pots should be raised, cleaned, and placed in the greenhouse. Greenhouse plants must now be taken in, and be gradually inured to winter treatment, by the free admission of air and abatement of water. Take up the Persian cyclamen, and pot it in loam, sand, and leaf-mould.

November.—Plant all bulbs, employing much sand about and above the bulbs. Protect fuchsias, if frost threaten. Screened leaves form the best substance to be placed as mulch. Dahlias should be taken up in airy and dry weather, when quite dry and clean: preserve the tubers in well-dried sand.

December.—Protect beds of tulips, hyacinths, and other choice bulbs or roots, with a layer of saw-dust mixed with sand, or with ashes. Saw-dust alone has been found the most effectual protector to the roots of potted plants in frames, the pots being plunged in it to the brims. If dry weather permit, lightly fork the surface of plots and borders; but at anyrate, if it be frosty, scatter some light manures around the stems of shrubs and the more tender plants; it will tend to enrich the ground.

Fruit.

THE FRUIT-GARDEN.

GENERAL MANAGEMENT.

FRUIT-TREES are either grown as independent plants in an orchard, in which case the tree is suffered very much to assume any height or bulk that nature permits; or they are trained upon walls, or constrained to grow in a particular manner upon artificial palings called *espaliers*. In whatever manner the tree is planted, or designed to grow, the tendency of the main stem and branches of the plant is upwards into the atmosphere, and of the chief roots, downwards into the soil. In general, the depth and spreading of the roots are proportional to the height and spreading of the branches, because the roots are the anchorage and food-seekers of the plant, and require a depth and compass of soil corresponding to the bulk of the tree and its demands for nourishment. It is therefore of the first importance not to stint fruit-trees of a depth and breadth of good sound mould adapted to their expected dimensions.

Trees or bushes planted close to walls should have a depth of soil in proportion to the height of the wall. If the wall be six feet high, the border beneath will require to be trenched two feet deep; and so on to a ten-feet wall, which should have at least three feet of free penetrable soil. The principle is, the deeper the soil, the less will the roots straggle. As already said, their tendency is chiefly downwards; and it is only because they cannot get far enough down, that they range abroad. Their object is to absorb nourishment wherever it can be obtained; and, abstractly considered, it is of little consequence whether this nourishment be procured beneath the main stem, or at ten yards' distance. But, practically, the gardener is concerned in keeping the roots from straggling, and interlacing, as with a net-work, the under-strata of his borders, thus impeding his operations, and perhaps robbing his culinary vegetables or flowering shrubs of a portion of their food.

It will therefore be observed that depth of available soil is as essential in fruit-tree culture as in any other department of gardening. Fruit-trees must never be excited by new and undecomposed manure. The material applied both before planting, and also while the tree is growing, should be loam, mixed with a thoroughly rotted compost of dung, leaves, and the like. Some persons, following an old prejudice, place a paving-stone at a certain depth beneath, to prevent the root of the tree from penetrating into the subsoil; but this is only waste of labour; for if the descent be counteracted, the roots will proceed laterally, and penetrate downwards as soon as they can conveniently do so. By giving a proper depth of soil, and keeping that soil in heart, no fear need be entertained for the tree receiving that injury from the subsoil which it was the object of the paving-stones and lined pits of our forefathers to prevent.

When we say that depth of soil is advantageous, it is necessary to guard against an impression being formed that deep planting is also required. In general, the roots of trees should be placed near the surface.

Mr M'Intosh, in his work on *The Orchard*, offers the following caution on this subject: 'Deep planting is an evil much to be guarded against; and many of the disappointments which have attended the fruit-grower may be traced to this cause. As some criterion for the guidance of the amateur, we would say, let every young fruit-tree, of whatever kind, be planted at least three inches above the ground-level—that is to say, let the part of the stem which was level with the surface while in the nursery, be kept three inches above the general surface of the ground when it is planted, and let the earth be heaped up to that height around it, for a couple of feet or so, in the form of a little hillock. Trees of larger size may be rather more elevated. This applies to soils of the ordinary description; but in damp soils the elevation should be still greater. When trees are set in a pit—which should always be a third larger in diameter than that of the extent of the roots, so that they may be all spread out to their full extent, without being doubled or turned round—they should be spread as regularly as possible, and the bottom should be made perfectly level; by this means the roots will have a horizontal direction given to them, which they will afterwards maintain. The intention of this arrangement is to induce them to extend themselves near the surface, and to prevent their extending downwards into a bad or cold subsoil.'

Grafting—Budding—Inarching.

Fruit-trees are propagated by means of seeds, cuttings, or layers. In the case of seedlings, it is always necessary to adopt the practice of grafting or budding, to insure the production of good fruit; and although these operations are usually performed in the nursery, and do not necessarily form part of the amateur's practice, still they are of sufficient interest to merit a detailed description.

Grafting, which is a practice of great antiquity, may be stated in principle to be the union of two individual plants in a growing state, through the medium of the circulating juices.

Gardeners assign various reasons for grafting: 1. The perpetuation of varieties of fruit, which could not be insured by sowing seed; 2. Increasing, with considerable rapidity, the number of trees of any desired sort; 3. Accelerating the fructification of trees which are tardy in producing their fruit; and 4. Changing the sorts of fruit of an old tree, and renewing its productiveness; for when a tree becomes old, but has still healthy and vigorous roots, and it is thought advisable to renew or improve its fruitful qualities, it is cut off across the lower part of the stem, and forms the *stock* on which *scions* are ingrafted, which scions become in time the fruit-bearing branches of the tree. The wild apple-tree, which bears only crabs, too sour to be eaten, forms one of the best stocks on which a graft can be put; and for this purpose it is grown by nurserymen from seeds. The notice of this fact leads to a consideration of what are the radical principles on which improvement is effected by grafting. On this intricate subject we subjoin the explanations of Dr Lindley: 'In proportion as the scion and stock approach each other closely in constitution, the less effect is produced by the latter; and, on the contrary, in proportion to the constitutional difference between the stock and the scion, is the effect of the former important. Thus when pears are grafted or budded on the wild species, apples upon crabs, plums upon plums, and peaches upon peaches or almonds, the scion is, in regard to fertility, exactly in the same state as if it had not been grafted at all; while, on the other hand, a great increase of fertility is the result of grafting pears upon quinces, peaches upon plums, apples upon white thorn, and the like. In these latter cases, the food absorbed from the earth by the root of the stock is communicated slowly and unwillingly to the scion; under no circumstance is the communication between the one and the other as free and perfect as if their natures had been more nearly the same; the sap is impeded in its ascent, and the proper juices are impeded in their descent, whence arises that accumulation of secretion which is sure to be attended with increased fertility. No other influence than this can be exercised by the stock upon the scion. Those who fancy that the contrary takes place—that the quince, for instance, communicates some portion of its austerity to the pear—can scarcely have considered the question physiologically, or they would have seen that the whole of the food communicated from the alburnum of the quince to that of the pear is in nearly the same state as it was when it entered the roots of the former. Whatever elaboration it undergoes must necessarily take place in the foliage of the pear—where, far from the influence of the quince, secretions natural to the variety go on with no more interruption than if the quince formed no part of the system of the individual.' It must be kept in view, however, that we have no very satisfactory course of experiments on record to shew the precise reciprocal influences of the graft and stock. For an instructive discussion of the subject, see Dr Lindley's paper in *Gardeners' Chronicle* of the 6th of June 1857.

Grafting is performed in two principal ways—scion or slip grafting, and grafting by approach, or inarching. The season for the operation is about the middle of March, when the sap is rising and the buds beginning to swell. The grafting should not take place immediately on cutting the scion: after removal from its parent stem, place it in the ground for a few days, so that it may be partially exhausted of its juices, and be more ready to receive the ascending sap from the stock. Keep it in dry ground, and not exposed to the sun. A scion may be brought safely from a distance by being stuck in a raw potato. Before applying to the stock, cut the extremity of the scion afresh.

Tongue-grafting, by which a tongue or slice raised in the sloping cut of the scion is inserted in a corresponding notch of the stock, is the more common method. The young stem of the stock is cut across, so that the scion which is added forms the stem of the future tree. The cut in both pieces requires to be smooth, and the joining so neat, that the bark on one side of the scion must be even with the bark of the stock. Having joined the two pieces, bandage them together with a flat strip of mat, but not so tightly as to prevent circulation or the expansion of the fibre. Over the bandage, plaster all round a handful of soft adhesive material, formed of clay, cow-dung, and chopped straw, taking care not to disturb the united edges. This mass will form a hardened lump, and may remain till the end of summer, when the union has become complete.

If the grafting has been properly performed, and other circumstances be favourable, the scion in two years will be in blossom, and yield a crop of fruit. What its quality will be, must depend on the nature of both stock and scion. If the scion be of a fine variety, it will remain so; and if the stock be well chosen, the quality may be slightly improved. The excellence of the scion, however, is the prime consideration, for it is the part which is immediately concerned in the elaboration of the descending sap or proper juice, upon which depends the flavour and quality of the fruit.

Speaking of the descending sap, it may be here observed that the thickening of this juice does not take place without the aid of heat and solar light; and thus, in cold wet situations, plants seldom produce so much fruit as in warm and dry ones. Cultivators bend the branches in training them against a wall, so as to prevent the too rapid descent of the sap, and to force it to accumulate in those places where they wish flower-buds to be produced. If a ring of bark be taken off a tree in spring, the sap will rise as usual; but when it begins to descend, a protuberance will be

formed just above the ring, occasioned by the accumulation of the sap. This explains why gardeners sometimes ring the branches of trees in order to throw them into fruit.

For an account of the process of *budding*, which is analogous to grafting, we refer to the number on THE FLOWER-GARDEN.

Inarching is an ingenious mode of grafting, by which one growing plant, without removal, is made to strike upon another plant, and thus form a union. It may be performed in various ways, as represented below. For

example, two branches of a tree (*a*) may be bent so as to meet and strike upon a wound in the main stem, by which a gap will be filled up; one growing tree (*b*) either from the ground or a pot, may be led to unite with another; or several suckers (*c*) may be led from the ground archwise to strike upon a point in the stem, thus bringing fresh aid to the productive part of the tree. By means such as these, quickset-hedges are sometimes thickened like a net-work, so as greatly to improve their appearance and protective qualities.

CULTURE OF FRUIT-TREES.

Having disposed of those operations that are common to most fruit-trees, we shall now proceed to describe in detail the various methods of culture adapted to the different kinds.

The Apple.

The apple-tree is of universal European growth, and, as a cultivated fruit, is believed to have been introduced into Britain by the Romans. It was much cultivated in the gardens of monasteries during the middle ages, and from that source the greater number of our cultivated varieties have drawn their origin. The apple-tree, if favoured by a good soil and climate, will live to a great age, two hundred years being not an unusual duration in a fruit-bearing condition. Some orchard apple-trees now existing in Herefordshire are said to be a thousand years old, while others were brought over by the Normans in the time of William the Conqueror.

The varieties of cultivated apples are now innumerable, several thousands being described in catalogues, but all may be classed into three groups—namely, apples for the *table*, or to be eaten raw; apples suitable for *baking* and other culinary purposes; and apples for *cider*. Table-apples are again subdivided into those which will keep, and those which will not. The choice kinds at present include the Ribstone pippin, which will keep till March, but is in its prime about Christmas; the Dowton nonpareil, scarlet pearmain, and Blenheim orange. The Keswick and Kentish codling and Hawthornden are early ripe, but the fruit will not keep beyond October. The nonsuch is a fine apple, and remains good in October. The old nonpareil is in every respect deserving of its title; its flavour is high and musky, and it keeps long; few apples bring such a high price in the market in February. Other choice long-keepers are, the scarlet nonpareil, the golden harvey or brandy apple, the winter pearmain, and the Easter apple, commonly called French crab. The best baking-apples are the Colvilles for early use; the rennets and pearmains for autumn; the russets and Padley's pippins for winter and spring. To this short list, hundreds might be added; but those who can grow what we have enumerated, and bring them to their full complement of bearing, can require no others as stock-trees. It must always be borne in mind, however, that what will succeed well in one garden may not do so in another, and that experience as to soil and climate, independently of advice from skilled neighbours, will in every case be necessary in the proper and profitable conducting of the fruit-garden.

For *cottage-gardens*, where the soil and situation are favourable for the production of the apple, the following sorts are recommended by Mr Thompson: Where the space will admit of only one tree, the best is the Ribstone pippin; where two, the Ribstone pippin and Dutch mignonne; where three, the Wormsley pippin, Ribstone pippin, and Dutch mignonne; where four, the Wormsley pippin, king of the pippins, Ribstone pippin, and Dutch mignonne; where five, the Wormsley pippin, king of the pippins, Ribstone pippin, old nonpareil, and Dowton nonpareil; where six, the Wormsley pippin, king of the pippins, Ribstone pippin, Alfreston, old nonpareil, and Dowton nonpareil; where seven, the Wormsley pippin, king of the pippins, Ribstone pippin, Alfreston, Dutch mignonne, old nonpareil, and Dowton nonpareil. Beyond this, Pennington's seedling and any other good sorts may be added. Mr Loudon observes, in the *Encyclopædia of Gardening*: 'It often happens that one or more trees can be trained against a cottage wall or roof, or against some wall appertaining to a cottage; in these cases, the proper sorts are, Ribstone pippins, old nonpareils, and if a large kitchen-apple be required, the Bedfordshire foundling. In situations liable to spring frosts, which so often kill the blossoms of the generality of apples, the Court pendu plat is recommendable, as its blossoms expand very late in the season. Under less favourable circumstances, where the Ribstone may not succeed, the Bedfordshire foundling will be a hardier substitute, or the king of the pippins, which is still hardier; the northern greening may be planted for late kitchen use. For an autumn-apple, perhaps none in this case is more to be recommended than the Keswick codling.' To these observations, we need only add, that the cottager will do well in all cases to prefer one or two copious-bearing trees to a number of fancy and fickle varieties.

Standards.—Pruning and Training.—Standards are those trees which grow independently in open ground, and are classed as Large and Dwarf Standards. The proper object of cultivation is to give figure to the tree, of whichever kind, and bring it to a fertile or mature condition. Apple and pear trees, as they approach to maturity, develop short *spurs* along the entire extent of the branches, and those spurs are the best in every respect which are produced naturally without the aid of the pruning-knife. But in addition to fruitful spurs, the trees produce a great number of superfluous wood-shoots, which, if not entirely removed, or at least so curtailed as to convert them to bearing spurs, would render the tree almost useless; in short, to effect prolific fruit-bearing, the shoots must be kept in subjection, or in the state of spurs. A recent writer on this subject observes: 'If a tree be a free grower, on a free stock, as the crab, or a strong pippin, from seed, all the leaders will be checked by shortening them back every year to a distance from the point of origin, which varies according to their strength; where they are very strong, the leading shoots should not be reduced more than within twelve or fifteen inches of their base; but when they are weaker, they may be

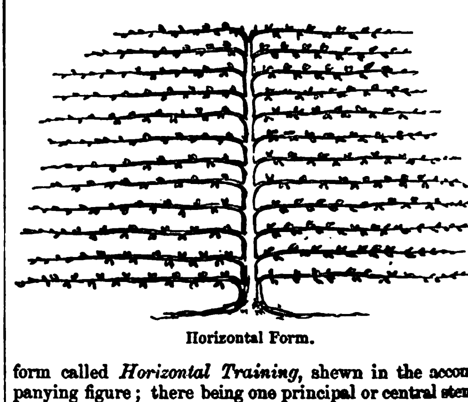
cut to within nine inches. By this means the onward growth of the branch is momentarily arrested, the ascending sap is impelled into the lateral buds, some of which will be sure to grow so slow as to become productive.'

The foregoing directions comprise a view of the theoretical principles of pruning, and afford an excellent groundwork for practice; but those who are strangers to the cultivation of fruit-trees, and, as such, undertake the management of an orchard, will be surprised and perplexed at the anomalies which continually present themselves. It will then be self-evident that gardening cannot, in its routine, be learned from books; that one tree assumes a certain mode of growth; another develops in an order which has not been foreseen or contemplated; one forms its fruitful spurs spontaneously, without solicitation or the adoption of means; while another, in despite of the most rigid foreshortening, continues for years to yield nothing but leafy shoots. Mr George Lindley has given excellent practical directions for pruning in his *Guide to the Orchard*, &c. He observes that 'dwarfs on *crab-stocks* are much more adapted for large and ponderous fruit than standards, as they not only produce larger fruit, but it is less likely to be blown down by high winds. Trees for this purpose should have their branches of an equal strength: those which have been grafted one year, or what are termed by nurserymen maiden plants, are the best; they should not be cut down when planted, but should stand a year, and then be headed down to the length of four or six inches, according to their strength; these will produce three or four shoots from each cut-down branch, which will be sufficient to form a head. At the end of the second year, two or three of the best placed of these from each branch should be selected, and shortened back to nine, twelve, or fifteen inches each, according to their strength, taking care to keep the head perfectly balanced, so that one side shall not be higher or more numerous in its branches than the other; and all must be kept as near as may be at an equal distance from each other. If this regularity in forming the head be attended to, and effected at first, there will be no difficulty in keeping it so afterwards, by observing either to prune that bud immediately on the inside next to the centre of the tree, or that immediately on the outside. By this means, viewing it from the centre, the branches will be produced in a perpendicular line from the eye; whereas, if pruned to a bud on the right or left side of the branch, the young shoot will be produced in the same direction; so that if the branches formed round a circle be not thus pruned to the eyes on the right successively, or the left successively, a very material difference will be found, and the regularity of the tree will be destroyed in one single year's pruning.'

What is here said refers only to the leading shoots which form the figure of the tree; others—side-shoots or laterals as they are termed—are developed, and these require constant regulation. 'In pruning these laterals or supernumeraries, they should be cut down to within an inch of the bottom, which will generally cause the surrounding eyes to form natural blossom spurs; but where the tree is in a vigorous state of growth, branches will probably be produced instead of spurs; if so, they must all be cut out close, except one, which must be shortened as before. In all winter-prunings, care must be taken to keep the spurs short and close, none of which should at any time exceed three inches; cutting out clean all the blank spurs, which have produced fruit the previous summer, to the next perfect bud below.'

It would perhaps be impossible for any writer to improve upon these directions generally; they comprise all the essentials for producing a balanced dwarf standard—that is, a tree low in stature, furnished with ten or twelve regular main branches, proceeding at a short distance from one central stem, each branch furnished from base to summit with fruitful spurs. But experience instructs the pruner not to expect too much, but to watch the figure which the tree affects, and the course of its supernumerary shoots. If it evince a decided tendency to form short spurs naturally at a very early period, he may prune short, as above directed; but if its habit be so luxuriant as to produce wood-shoots after each pruning, it will be wise to defer the summer-cutting of the spring-shoots till the middle of July, instead of performing it at or before midsummer; and then either to snap the shoots or to cut them to a bud situated at least five inches from their base. This pruning, late as is the season, will generally cause each shoot to break its leading eye; in August, therefore, this new shoot is to be checked by nipping off its point; and finally, in September, the spring-shoot is again to be cut at the eye, below the one at which it was first pruned in July. In this way the vigour of the tree will be moderated, and several of the lower buds will probably enlarge, while the leading bud only expands into a growing shoot. If these hints be understood and acted upon, a young pruner will experimentally be taught to apply them, and thereby acquire the tact to discover the constitution of his trees individually, and to coax them into a condition of maturity. At the winter regulation, when the buds begin to swell, it will be easy to discern the fruitful eyes; and where these are discerned, the shoot projecting beyond them is entirely amputated; and this may be done with safety, for spurs, when once fully formed, rarely break into barren shoots, though one of the eyes may do so.

Wall-training.—The circumstance of apple-trees and other kinds of fruit-trees producing fruit only on the outer parts, which are freely exposed to the sun and air, has led to numerous contrivances for exposing the inner as well as the outer stems. One method, as is well known, is the training of the tree in a flat shape against a wall—a plan also advantageous for enjoying the heat, which the wall receives and radiates against the branches. The training of trees upon a wall is a very artificial process, but by no means inimical to their healthy growth, being, on the contrary, conducive to their fertility, while it also facilitates the ripening of the fruit. Much attention is required, however, to carry out the system, and prevent the branches escaping from their constrained situation; and in the annual prunings, the gardener must keep before him the habit of the particular tree, and the form desired. One great point is to induce or preserve equilibrium in the growth of the tree, so as to give it ultimately a symmetrical form. Numerous methods of training have been introduced, but the best for general purposes, and that which has been most extensively employed in this country, is the

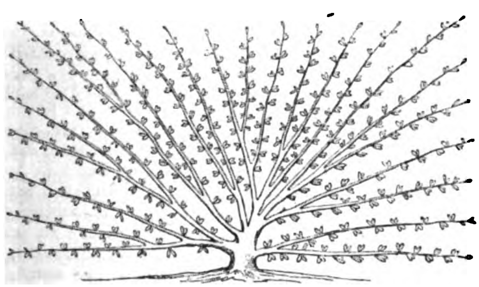


Horizontal Form.

form called *Horizontal Training*, shewn in the accompanying figure; there being one principal or central stem, from which side-branches diverge at right angles, and at regular distances—about ten inches—apart. This form is best adapted for strong growing trees, such as the Ribstone Pippin Apple, or Gansel's Bergamot Pear; but

it may be so modified as to suit the more twiggy kinds. It is thus described by Dr Neill, the 'Father of Scottish Gardening:' 'In order to produce this form, the vertical shoot is, in trees of ordinary vigour, cut back every winter to within fourteen inches of the highest pair of branches; a number of shoots are produced in the beginning of each summer, out of which three are selected; one is trained in the original direction of the stem, and one on each side of it, parallel to the base of the wall. By pinching off the point of the leading shoot about midsummer, another pair may be obtained in autumn. In luxuriant trees, the vertical shoot may be left two feet in length, by which means, and by summer-pruning, four pair of branches may sometimes be added in one season. The great object at first ought to be to draw the stem upwards: when it has reached the top of the wall, it is made to divaricate into two; and the tree thus completed as to its height, is henceforth suffered to increase in breadth only.'

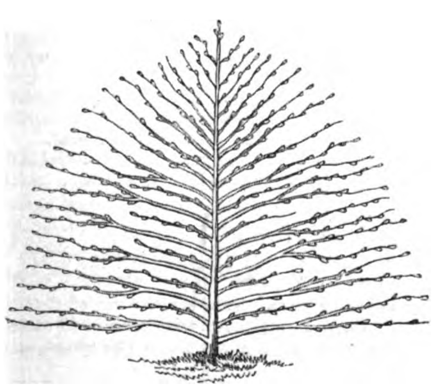
The next form of training we shall notice is called *Fan-training*, from the branches spreading out from a common origin; there being no prolonged main axis as in horizontal-training. The accompanying wood-cut will



Fan Form.

serve to illustrate this form better than a lengthened description. Of course this method can only be adopted successfully where there are lofty walls.

A kind of training called half-fan has been brought into notice, but is, in fact, a modification of the horizontal form, with this difference, that the branches form a more or less acute angle with the stem, which is supposed to favour the natural flow of sap. One of the forms of this method is represented below.



Half-fan.

Espaliers.—These are rails generally formed of upright and cross bars of wood, but sometimes made of cast iron. The best are of wood, and from four to five feet in height. To these the trees are trained as on a wall, with this difference, that instead of being nailed, the branches are usually tied; the fastenings are tar-twine or strips of bast. The situation of espaliers is generally along the sides of walks; and if the trees be carefully trained, they have a neat effect. Care must be taken that they do not prevent the sun and air from reaching the kitchen vegetables. When properly managed and well exposed, espalier-trees 'generally produce excellent fruit, the sun and air having access to both sides of the tree: they commonly afford abundant crops, and the fruit is not apt to be shaken by high winds. Further, they tend to hide the crops of culinary vegetables from the eye, and to render the kitchen-garden as pleasant as an avenue in the shrubbery.'

Espaliers are not necessarily confined to the hedge-like form in which they usually appear. In the Experimental Garden, Edinburgh, examples of more elegant forms may be seen, in some of which the trees are trained on inclined rails, others in a horizontal tabular form, while some trees are made to assume the form of a cup, &c.

The following practical hints on espalier-training, by the author of the *Manse-garden*, appear so eminently useful, that we take the liberty of giving them a place here. First, as to cultivation: 'Have the ground well trenched and manured [taking a crop of vegetables the first season], and plant the trees three or four feet from the walk, and twice as near to one another as they should afterwards be when full-grown. The reasons for this close planting are, that the value of a few crops is more than the expense of the trees; your rails are sooner covered; and when the trees begin to meet and incommode one another, you can then, having ascertained their various qualities, give scope to the best, by diminishing or rooting out the less worthy. For one or two years after the meeting has taken place, you may delay the pain of execution by allowing the young shoots to pass one another on the opposite sides of the rails. To incur no more expense than is necessary, the stakes may be placed two feet apart, in which case the annual shoots will require to be conducted from one resting-place to another by pieces of lath or wild-brier, or willow of two years' growth. These conductors require a firm and separate tying, distinct from that which fastens more loosely the living wood; they thus give strength to the rails, and provide for straighter training than is commonly done by having the stakes twice as thickly set, and, consequently, at double the expense of timber.

'Supplementary to both wall and espaliers is the following device, which has proved eminently successful: Supposing that you have more garden-ground than is necessary for the supply of vegetables, and that some part of it may be spared for a green shady walk amidst shrubs mingled with standard fruit-trees, on the south side of a row of evergreens, impervious to the eye, let a dry stone-wall be raised to the height of four or five feet, and coped with large stones, merely for strength and durability. Plant this on the north side with ivy, to assist the screen of shrubs, and in a short time not one stone will appear. From the south side take away all the good soil to a depth of two feet, a breadth of five feet, and a length equal to that of the wall, which may be sixty or a hundred feet, as you find convenient. This excavation, it is to be understood, runs close by the building, the foundation of which must of course have been secured by perhaps a foot of depth, and which will yet be uninjured, as the stones that cast up in removing the earth will immediately be thrown to the base in room of the materials taken away. Thus an effectual provision is made against the springing up of docks, nettles, or other troublesome weeds; the earth removed will be an invaluable treasure, whether for making compost or helping a thin soil; and the excavation itself will afford a most convenient receptacle for the immense quantities of stones which occur in trenching or raking the garden. Suppose the filling up in this manner to be nearly completed, let a row of large thin stones, set on edge, run along the southern

boundary, and rise two or three inches above the surface of the ground. This will serve to keep the mass of stones distinct from the earth, that there may be no mingling in the process of digging. You have then on the one side of this excavation the low edging, and on the other a wall of four or five feet; and the design is, in the course of time, to fill up, with the riddlings of the garden or with clean stones, in whatever way, the whole space from the summit of the low edging to the top of the wall, to present an inclined plane facing the south, and nearly at right angles to the rays of the sun. On this [which is, in reality, a mound leaning against a wall] fruit-trees are to be trained. Before the bank is completed to its proper slope, the trees may be planted along the southern boundary, and trained for two or three years upon poles laid from the edging to the top of the wall, according to their future destination. When the surface of the sloping bank is raised within an inch or two of its proper height, let a layer of coarse sifted gravel be laid on the top. This will much improve the appearance, and increase the reflected heat; and being free from small sand and earthy particles, will give no birth to annual weeds.

'For the purpose of training, should peaches or apricots be planted, a close trellis will be requisite; but apples or pears will require nothing more than common espalier-rails laid on the gravel, and held in their places by two slight spars running across, one at the top, and the other at the bottom. In the meantime, the ivy produces a beautiful and beneficial effect, surmounting the wall, and adding to the closeness of shelter caused by the evergreen shrubs. It should be clipped along the top after the manner of box-edging. Nothing can exceed the real snugness of the trees so placed, or the beauty of their glowing blossoms spread out under the eye; and the quality of the fruit comes fully up to the theoretical advantages with which it is favoured. The heat is undoubtedly much greater than that of the best wall; and the open flowers find, in their humble height, a shelter, like the daisy of the field, from the sweeping blast, which often scatters the petals of a higher tree like a shower of snow. Experience has fully proved the suitableness of this contrivance to all elevated situations. In some places very low and warm, the heat, so powerfully reflected, might possibly be too great; but in that case, figs and nectarines might be so exposed, and would certainly take all that they can get.'

The Pear.

The pear-tree, like the apple, is found in a wild state in all parts of Europe, and has been similarly domesticated and improved into many fine varieties. The tendency of the tree is to a handsome pyramidal form. It is much longer in attaining maturity than the apple-tree; and on a dry soil, it will survive and continue fruitful for centuries. The tree may be propagated by seeds; but grafting is necessary to insure good fruit.

The observations already offered respecting soil for apple-trees, apply equally to the pear. The pruning, however, is different, for the pear is a very independent growing tree, and, as a standard, will assume its own natural figure in opposition to all restraint. All branches which lash one another must be removed; but, unless the pruner cut and deform his trees in his attempts to create fruitful spurs, there will seldom be a redundancy of wood. A little foreshortening or disbudding in the spring and summer may be useful; but in general, as the pear can seldom become fruitful under seven or eight years from the grafting or budding, it will be prudent to watch the gradual development of the natural spurs, and to cut back the laterals to them when formed, and not before. Mr Knight pruned very little, shortening the main shoots occasionally, not sooner than July. He says: 'I would recommend the knife to be little used upon the young pear-trees, particularly upon the horizontal branches. As a general rule for pruning trees that are to be kept low in gardens, I recommend the upright shoots to be shortened about the beginning of July.'

Many varieties of pear are enumerated in catalogues, all differing from each other in their qualities, time of ripening, or other particulars. Among the finest sorts may be mentioned the Jargonelle, Marie Louise, Beurré de Capiaumont, Muscadelle, Bonchrétien, St Germain, Rousselet, Wilding, Beurré Diel, Glout Morceau, Easter Beurré, and Beurré Rance. The word *beurré*, which here occurs several times, is from the French word for butter; and that, as well as the other names, shew how much we are indebted to our continental neighbours for perfecting this delicious fruit. The summer, autumn, and winter Bergamots are not excelled for rich muskiness of flavour. For a large supply, where much care is not given, the jargonelle will be preferred. The pear requires a warmer climate than the apple; hence some of the finer sorts, which grow well as standards in the south of England, will require a wall and shelter in northern or more keen situations. Any sorts worth cultivating should have a rich aromatic flavour, and be either of the melting kind (*beurré*), or firm and crisp, like the winter Bergamots.

Orchards.

An orchard is a piece of ground specially devoted to the rearing of fruit-trees, principally apples and pears, and is frequently an appendage to the English farm and manor-house. It should be a well-fenced enclosure, and if there be room for choice, its situation ought to be on the side of a dry knoll sloping to the south; the best soil is a fresh sandy loam, of eighteen inches in depth or upwards, reposing on a subsoil of dry gravel or rock. If the ground be wet, it must be thoroughly drained in the first place, as no fruit-tree can answer its purpose if the soil be otherwise than dry.

Shelter is necessary to orchards against the autumnal south-west winds. This is best obtained by high hedges or forest-trees planted on that side. Winds from any other quarter need not be so much dreaded. Sheltering hills at some distance are advantageous; but it must always be kept in view that a free exposure to light and air is very necessary. Many orchards are almost barren, and the trees covered with lichen, from their being too much sheltered, and deprived of a free current of air.

If an orchard is a pasture for sheep, cows, or other cattle, the trees to be planted in it must be standards—that is, trees trained with a clear stem six or seven feet high, from the top of which the branches diverge, out of the reach of cattle. Sometimes the stocks are first planted, and when fairly established, are *worked*—that is, grafted or budded at the desired height.

If an orchard is to be formed out of an arable-field, the ground may be prepared by the plough, laid into bands or ridges of eight yards wide, the trees to occupy the middle or crown of each ridge, these lying south and north. The trees should be planted in right lines, five, six, or eight yards asunder; and the whole area surrounded by a hawthorn hedge. When the trees are planted—which should be about the end of October—the ground may be laid down with a crop of barley or oats, with grass and clover seeds in the spring, and so remain.

If an orchard is to be formed in a grass-field, the ground is drained, if necessary, and enclosed with a hedge and ditch as above. The trees are either planted in trenched pits or in trenched borders—that is, borders six feet wide are traced south and north, and regularly trenched fifteen inches deep, the turf being turned to the bottom. Along the middle of these borders the trees are put in at the distances already mentioned. This done, the broken ground is sown down with grass-seeds, and the trees staked and protected against cattle, if

they are in any danger. The pits, six feet square, are trenched and planted in like manner. In planting the trees, the ordinary care must be bestowed as well in taking them up as replanting. Each should be set on a little mound of the finest of the soil, on which the roots should be regularly spread, and kept near the surface —for deep planting must be carefully avoided; the uppermost fringe of roots should just be within the turf, but no deeper; and they should be encouraged to take a horizontal rather than a downward direction. Orchards planted in either of these methods answer very well, if care is taken of the trees till they are fairly established, and can protect themselves.

The fruits chosen for such orchards are apples, pears, plums, and cherries, and of these, such varieties as are known to thrive, and are most fruitful in the neighbourhood; for all fruits are not equally adapted to the same locality, and this is a point deserving the serious consideration of the planter. Orchards of this kind are planted chiefly with a view to the service of a family, any redundance being sent to market or sold on the trees to the fruit-monger; but when fruit-trees are planted as a special source of profit, a very different plan requires to be followed.

An acre or two of suitable land, with a proper exposure, is fixed on; the whole is trenched fifteen inches deep, and thoroughly drained, if necessary. The surface is levelled, and laid into beds ranging south and north, and about twelve feet wide; along the middle of these the trees are planted, and the intervals are occupied by two rows of small fruits—such as gooseberries, currants, or raspberries. Some of the intervals may have a row of filberts introduced, which, when kept as low bushes, are as profitable as any other kind of orchard-fruit. Such an orchard is intended to be a perfect thicket of fruit-trees: all, whether yielding large or small fruit, must be kept as dwarfs, and trained in the *bush-form*. Of course, the sorts which are naturally of a dwarfish habit are preferred, and if not dwarfish by nature, they must be made so by art. The bush-form is obtained by encouraging the lateral growth of the branches, and stopping those which have a tendency to grow upright. A sufficient number of branches is gained by pruning while the trees are young, and so disposed that they may aggregately form a rotund, compact, but not overcrowded head, shading a circle twelve or fourteen feet in diameter, more or less, according to the fruitfulness or individual strength and habit of the tree. This close planting and low stature of the trees render them a shelter to each other, both against the frosty winds at the time of flowering, and against the equinoctial gales of autumn. In dry summers, a mulching of half-decayed littery-dung is spread under the trees, and hoed in during the winter. Strawberries are introduced when the trees are young, but the ground must not be exhausted by surface-cropping.

The success of such a fruit-garden depends very much on a proper selection of the kinds, and on the skill of the manager in keeping the trees fruitful and dwarfish.

In Herefordshire, Devonshire, and adjoining districts in England, orchards are maintained principally for manufacturing a beverage from their produce. *Cider* is the liquor made from apples; the trees in most estimation for the purpose being the New Foxwhelp, the Wilding, the Cherry Pearmain, and the Yellow and Red Norman. When the ripened apples have been shaken from the trees, they are allowed to remain in heaps for a month or so on the ground, to become mellow; after which the process of manufacture into cider commences. *Perry*, or the liquor from pears, is also a pleasant and wholesome beverage, and in some instances almost approaches the quality of sparkling champagne. The most austere varieties of the pear, unfit for the table, answer best for this purpose; and it is thought that a mixture of the wild pear with the cultivated sorts makes a peculiarly fine liquor.

Quince and Medlar.

These two fruits are more botanical curiosities than useful inhabitants of the fruit-garden.

The *Quince* is classed by botanists with the apple and pear, and these are often grafted on quince-stocks, which confirms their consanguinity. It is said to be a native of Eastern Europe, and to grow wild on the banks of the Danube. It was introduced into Britain from the isle of Candia, but is not much used—the fruit in its raw state having a peculiar disagreeable smell and an austere taste. It is sometimes employed to give flavour to apples in pies and tarts, and is occasionally made into a marmalade, which is much used in the south of France, where the quince is extensively cultivated. The *Medlar* is also a native of South-eastern Europe. It has considerable flavour, but this is seldom developed, even in its ripe state, on the tree, and the fruit is therefore gathered and laid aside until it begins to change or decay, and then only is it fit to be eaten.

Peach and Nectarine.

Both are natives of the East, introduced from Persia in the year 1562, and extensively cultivated since that

period. Each exhibits two leading sub-varieties—namely, those in which the stone parts freely from the pulp, or *free-stones;* and those with flesh adhering to the stone, and therefore termed *cling-stones.*

The peach and nectarine (*Amygdalus Persica*) can be raised by sowing the stones, and excellent varieties have been so obtained; but as there is no certainty of what a seedling may ultimately become, it is not prudent to trust to this mode of propagation. Budding must therefore be resorted to. The peach and nectarine are seldom grafted; it is usual to select buds of trees that are approved bearers and of fertile habits, and to insert them into young vigorous stocks of the plum or almond. Nurserymen raise their trees in this way, preferring the plum-stock; the operation is performed late in July or early in August. The buds swell, but remain torpid till the spring of the following year, at which time the head of each budded tree is cut back to an inch above the inserted bud, which then expands, and forms one or more shoots; in general, the nurseryman prunes and trains them into form during the two succeeding years, when they are sold as trained trees. Either horizontal or fan training—as already described under the apple—may be adopted for the peach and nectarine, which must always be grown on a sheltered wall.

The peach produces its fruit upon the spring-wood of the previous year, and occasionally, also, if the habit of the tree be very vigorous, upon secondary shoots from that wood; but this is by no means desirable under ordinary circumstances, for it proves that the tree is too luxuriant in young wood, which, being developed after midsummer, can scarcely become duly mature. A tree cannot be expected to produce or support a crop of fruit in a period short of four or five years from the budding; but during that period the art of the gardener should be employed to lay in six or more regular branches to the right and left, which will form the skeleton or figure of the tree, and remain the

permanent supporters of the young bearing-wood. In the fan-method of training, secondary fruitful shoots are permitted to form at the under as well as the upper sides of these main branches; but in horizontal training, the fertile secondaries are led off from the upper sides only; all those which break from the front, or from the back next the wall, or from the under side, are obliterated as they appear, either by pinching them off with the finger and thumb, or by amputation with a sharp knife. The quantity of wood to be retained, year after year, so as to obtain a regularly increasing proportion of fruit, without redundant wood, is chiefly regulated by the judicious use of the knife in disbudding.

We will suppose the example of a tree trained in the nursery during two years, then planted in October against a wall fronting the south or south-east, and cut back in February following, so as to leave all its branches about six inches long. The shoots of the first spring form the bases of the permanent branches, and are to be nailed, as they advance, in the most regular order, leaving them at their full length till February of the second year, when the strength and condition of the tree are to be consulted. As a first rule, we are taught, and experience sanctions the rule, 'that every shoot is to be shortened in proportion to its strength, by pruning to the point where the wood is firm and well ripened, by which all the pithy wood is removed, causing a supply of that which is better ripened for the ensuing year.' But in order to facilitate the ripening of the wood, it must be trained thin, retaining those shoots only that may be required for the ensuing year. After two years' growth in a good soil, we may reasonably expect that six or eight permanent shoots, a yard or four feet in length, will be formed and trained in, on each hand, and that all these branches are furnished with three or more secondaries, laid in at nearly equal distances from one another, and which, by the end of June, may be a foot or more in length. The tree will continue to grow till the end of August; but disbudding must be effected repeatedly, so as to leave it in the form and condition just described. It has then become a bearing-tree, which condition implies a series of strong woody branches of two, three, or more years old, that have produced other shoots in the spring, which, when ripe, are of a deep reddish-brown tint on the sunny side. These latter are the fruitful shoots, and they never bear twice; but if neglected, run on to an uncertain length, sending forth other weak laterals, which might indeed bear a little fruit, but such as could never compensate for the ruin, or at least disfiguration of the tree. It is a maxim among good pruners, that a peach-tree should be *green* throughout or all over—that is, every space, even close to the main stem, has one or more leafy and fertile shoots. This maxim would be violated in two seasons were all the shoots permitted to extend themselves.

The bearing-shoots, therefore, must be shortened to twelve or fourteen inches, if strong; and the weaker to eight or ten inches, or even to half that length, if very slender. The pruner should cut sloping from behind. In furnishing a tree, it is not needful to cut away the wood-shoots as useless; because by pruning back to an eye seated rather low on the shoot, two good fertile shoots may be provided in lieu of a barren one. A single sharp-pointed eye is the origin of a wood-shoot; the blossom-bud is more bulky and rounded; but by deferring the winter regulation till late in February, the condition of the two will be no longer doubtful.

When it has once been so pruned, the leading branch will break its extreme bud, which will thus elongate that branch; and the fruitful laterals will also develop several minor shoots. It is from the last that a selection must be made to effect two objects of the greatest importance. The first is, to attract the sap along the entire shoot, in order to nourish the young fruit upon it; and this will require that the shoot at the extreme point, or at least one beyond the uppermost fruit, be permitted to extend itself, and be nailed securely to the wall, when it shall have acquired some strength and toughness. The second object is, to provide a shoot to succeed the one now bearing fruit; and in doing this, the lowest should be selected, because it will, by its situation, replace the present shoot in a manner most conformable with the gardener's maxim before adduced, and tend to keep the tree compact and fertile. A third shoot ought also to be retained to guard against emergency or accident; all the others should be removed by disbudding early in May. In July also, a general regulation must take place; when, by removing useless shoots, and nailing those retained, the fruit will be duly exposed to the sun's rays. Thus the growth of shoots and fruit proceeds; and if regularity and order be maintained, the tree will, year after year, elongate, and add branch to branch, retaining complete verdure throughout. A few lines from *The Guide*, by G. Lindley, will suffice to complete our concise directions: 'Should young shoots, indicating extraordinary vigour, anywhere make their appearance, they should be immediately cut out, unless where a vacant part of the wall can be filled up; because an excess of vigour in one part of the tree cannot be supported without detriment to the other. Peach-trees, when in a state of health and vigour, generally throw out laterals from their stronger shoots; when this is the case, they should not be cut off close, but shortened to the last eye nearest the branch; and if there is room, one or two of those first produced may be nailed to the wall, or the middle shoot may be cut out, leaving the two lowest laterals, and allowing them to take its place—thus frequently obtaining two fruit-bearing branches, when the main shoot would in all probability have been wholly unproductive.

'In the thinning of the fruit of peaches and nectarines, and indeed any other drupaceous fruit, it is necessary to proceed with caution, as it is apt to fall off after having attained a considerable size. In order, therefore, to secure a crop, it will be the best way to thin them at three separate times: the first, as soon as the fruit is of the size of a hazel-nut; the second, when of the size of a small walnut; and the third, as soon as the stone has become hardened; after this, it rarely happens that either peach or nectarine falls off before it is matured.'

Peach-trees are liable to be molested by insects and mildew; the former are usually species of Aphis, commonly called *green-fly*. In some cases the trees attacked suffer to an extraordinary degree, insomuch that the crop dwindles and the growth of the trees is checked—three or four distinct broods succeeding each other. Fumigation and washing with tobacco-water are the only remedies.

With respect to soil and preparation of border, what we have said respecting the *apple* applies strictly to the peach. As wall-peaches must have a border, we can devise no plan more effectual or simple than that of clearing out a space of the required length, of eight to twelve feet in breadth, the depth of soil at the wall to be twenty inches, sloping to fifteen inches—making a fall of five inches from back to front. The bottom of the bed being properly prepared, the bed itself should consist of the rich, but not clayey loam and turf, of a common or pasture, having in it no manure whatever. The trees may indeed be top-dressed every winter with littery manure a yard or more round the boles, and so deep as to protect their roots from frost. It will also be a great preventive of drought in summer; and of this any one may satisfy himself by raising the mulch in the very driest weather, when the soil under it will be seen black and moist, though in other parts it be parched to aridity. The fruit is said to be one month accelerated, and its value proportionably enhanced, by growing a tree in a pit of twenty-four feet long, sixty

inches deep at the back wall, and thirty inches at the front. The lights will thus obtain a sufficient slope, if their length be seven feet. Hundreds of fine fruit can be produced in July or August by one tree; but great watchfulness will be required about the period of blooming, to check the ravages of the aphides in their earliest approaches; by three days' neglect, we have seen the destruction of a crop, and the ruin of all the bearing-wood of the year, in despite of every usual application. A strong lining, twice renewed between February and June, will greatly accelerate the advance of the fruit.

Selection of a few of the finest Peaches.

The trees marked thus (*) are suitable to the Highlands of Scotland.

Some interesting details have been given by Mr H. Bailey (*Gar. Chro.*, April 4, 1857) of the system of peach-culture adopted at Montreuil, the village celebrated for producing fine fruit for the supply of the Paris market. The walls are eight or ten feet high, and white, being coated with plaster; the soil, a brown calcareous loam, resting on limestone rock, and therefore well drained, which is essential to peach-culture. Large heaps of the sweepings of the streets of Paris were lying in the lanes, ready to enrich the peach-borders; but the point we wish particularly to call attention to is, that the walls on which the trees are trained have a broad projecting eave of thatch, which is made still wider during the prevalence of spring frosts. In England, and especially in Scotland, our wall-fruits suffer so much from spring frosts, that any hints on this subject are valuable. In some of our best gardens, movable canvas screens are employed; and by means of these, combined with the Montreuil coping, we may almost effectually guard against all such injuries.

The Apricot.

The apricot (*Prunus Armeniaca*) is a native of Caucasus and China. It partakes of the habits of the plum and peach. It is multiplied by budding, either upon the common plum or the mussel plum. Lindley says that it is usual to bud the *Moor-park* upon the former; but he is persuaded that the tree would be better, and endure longer, were it budded upon the mussel; and if he be correct in this, we may safely assert that all the best apricots will succeed upon that stock without having recourse to any other. The operation of budding, like that of grafting, may be most readily acquired by observing the practice of a good budder. The season of budding is comprised between the third week of July and the 16th of August, and showery weather is propitious. The buds should be selected from shoots of the spring-wood; and in taking them off, a piece of bark one inch and a half long should be retained, from which the strip of wood it contains ought to detach itself freely, without bringing with it the eye of the bud. This eye or point is a vital organ, without which a bud cannot grow. This remark applies to every kind of bud, whether it be that of the apple, pear, peach, or any of their kindred; or of any ornamental tree or shrub which admits of being thus propagated.

The best varieties of apricot are—1. Breda, a very rich juicy fruit; 2. Moor-park, of high flavour, and also pretty large; 3. Royal, a French sort, earlier than Moor-park; 4. The Roman, hardy, and an abundant bearer, but the fruit is fit only for preserving.

As to pruning and training, when the figure of the tree is formed by having three or four branches proceeding from a main stem, each is shortened, soon after the leaves fall, to six inches, in order to obtain new branches. These are secured to the wall in May or June, at five or six inches' distance from one another, removing all supernumeraries. At the second winter-pruning, the leading shoots may be cut back to ten inches, the others growing upon them to six inches, more or less, as position and strength indicate. In May or June following, more wood is laid in from each branch; and thus, by disbudding and winter-shortening, a regularly formed head is obtained, upon the shoots of which short fruitful spurs are duly and progressively developed. In all winter-prunings and curtailments, the longest shoot that is retained ought not to exceed eighteen inches in length; thence diminishing, according to the strength of each, to nine, or even six inches.

The Plum.

The common sloe of Britain may be cited as an example of the genus *Prunus;* but those rich and luscious fruits which have been so long cultivated throughout Europe are of Eastern origin, being varieties of *P. domestica*. Plums are propagated by budding upon the common plum-stock; and for standards, the insertion is made nine inches from the ground, when, under favourable circumstances, the buds will produce vigorous shoots, standard high the first year. Open standards require little attention; they should be divested of all the superfluous shoots by pruning them out close to their origin, just before the season of spring-growth. But wall-trees and espaliers are to be treated as espalier pear-trees—that is, by training them with a central stem, and a series of horizontal branches proceeding from it on each side, nine inches apart. These branches are not to be shortened; and the spurs which form naturally upon them are to be kept short and compact as they advance in length. Artificial spurs may be obtained by July foreshortening; but as fertility is promoted by whatever checks the luxuriance of the wood, it will, we think, be preferable to train in the supernumerary laterals, depressing them below the horizontal level till some natural spurs are formed near their origin, and then to cut the shoots back to the lowest spur.

The plum ripens in September and October. Of the earlier dessert-plums, the Green Gage and the Orleans are the best. Coe's Golden Drop comes into season in October; and for preserving, we name the Winesour, the two varieties of Magnum Bonum, and the Damson. The Imperatrice is the best late plum, being delicious in November. Lawsons' Golden Gage Plum is a beautiful fruit, which is beginning to come into notice. The Victoria is also a handsome sort, as frequently shewn at our horticultural exhibitions. Plums are used at desserts, in tarts, and preserves; and, when dried, form the well-known *prunes* of the fruiterer. The fruit of the sloe (*P. spinosa*), when ripe, makes a good preserve.

The Cherry.

The cherry-tree, or *Cerasus*, has been known as a cultivated tree for at least three centuries; orchards, the produce of which was sold at a high price in the year 1540, existing to a large extent in Kent. This circumstance conferred the name of Kentish cherry on that peculiar kind. There are between 200 or 300 varieties, among which the best for general cultivation are the Kentish, the May-duke, and Morello. All may be grown as standards, but the May-duke and Morello produce larger fruit when trained against a wall.

Standard-trees form their own spurs, and require only a little thinning out of superfluous branches; but wall-trees must be treated as the apricot and plum, avoiding, however, to shorten the leading branches. The Morello requires a somewhat different treatment, because it not only bears on spurs, but, like the peach, on young wood of the last spring. Mr Rogers offers some remarks, which are deserving of attention. In

the gardens of which he had the charge, 'a north wall ten feet high had a border twelve feet wide, and very shallow, reposing on loose or rubble rock. The soil was a dark hazelly loam, of rather inferior quality: the roots were very near the surface, those nearest the stem actually above it. Five trees were originally planted, but subsequently the second and fourth were removed, leaving the centre tree at thirty-two feet from the end ones. Even at this distance the branches met; and in their progress, being kept very thin of leaf-bearing wood, the crops were magnificent.' The trees were simply planted on the natural surface of unprepared ground, without any manure or deep trenching. 'Neither was this border ever dug with spades, but slightly stirred with blunt forks, and having a little well-rotted horse-dung bestowed every second or third year. There cannot be a more mistaken notion and injurious practice than overloading and poisoning the fruit-borders with rich dung. In the early training of the Morello, the knife should be used freely, to gain a sufficient number of leading branches—thinning out the laterals, but never shortening them.'

The cherry-tree grows to a large size, and its wood is highly valued by turners and musical instrument-makers, from its suitableness for being bored and formed into smooth tubes; in the luxurious East, it is much used for the tubes of tobacco-pipes. The fruit of the cherry seems less impaired by growing in a wild state than other garden-fruits. In Scotland, the wild cherries, called *geans*, are small, but of fine flavour; and in Germany, the favourite liquor, *kirschwasser*, is distilled from the juice of this species of fruit. The liquor called *cherry-brandy* is made by putting the best black varieties in brandy. *Noyeau* is a liquor flavoured by the kernels of the *C. occidentalis;* and a large black cherry is employed in the manufacture of the *ratafia* of Grenoble. The *maraschino* of Zara is made from a peculiar kind cultivated in Dalmatia.

The Currant.

The currant is a native of Britain. Currant shrubs prosper only in cool climates, and they are somewhat arbitrary in their choice of a situation even in our own moist country; they grow to an astonishing perfection in the rich moist vales of the middle counties, but the berries dwindle in hot and arid situations. Manure can be advantageously and freely applied as a top-dressing in November, to remain on the surface till after the pruning in February, when it should be lightly forked into the soil without disturbing the roots.

The following are the most esteemed sorts in general cultivation: Common red, red Dutch, Knight's sweet red, champagne, common white, Dutch white, common black, and black Naples.

Mr Knight raised three or four hundred bushes from seeds in the course of his scientific experiments upon crossings, but of these very few excelled their parents. One of them, the red crystal, is superior in all respects. We have also raised currants from seeds, and have thus been instructed that seven or more years elapse ere the plants become fruitful, and therefore that propagation by cuttings is greatly preferable. Take cuttings of the young spring-wood, with a small heel of the older wood attached to it; divest it of all the buds excepting five of the uppermost and those of the heel; dibble holes six inches deep in a shady bed or border, and fix a cutting firmly in each hole, by pressure and watering. They succeed perfectly if planted in August, provided they be kept moist and entirely shaded, or in a north aspect; but the season extends thence to the beginning of March. The soil should be rich and light. Cuttings may be placed at first where they are intended to remain, or they may be transplanted after they become rooted plants, cutting away all but the upper whorl of roots: in either case, cut back to two or three buds the shoots made the first spring, and subsequently prune on every side at an outside bud, to make the bush spread at top, and render it open towards the centre.

Prune for fruit just after the buds begin to swell—never before February, or the birds will reduce the expected crop; and in pruning, shorten all the leaders and spur in the laterals, till the bushes appear like deformed masses of scrubby twigs. By these spurrings and shortenings, the bushes progress somewhat slowly, but the fruit is produced in massive clusters from the numerous spurs. The skeleton of each bush ought to consist of nine, twelve, or fifteen bearing branches, diverging at equal distances from three lower short limbs, which emerge from one main central stem; this is the best form of a neat bush, and the knife should be exercised to keep it open in the middle. If the spring-shoots push very vigorously, the first high wind generally breaks down more than half of them; but this natural pruning is frequently advantageous. The black currant requires a still more moist and cool site, and that the wood be kept young, but never pruned or spurred. Whatever shoots become black and scaly must be cut entirely out, leaving those bearing branches only which are of a delicate brown colour. The trees require frequent renewal, by taking vigorous cuttings, for old wood produces small berries. If the soil and site be congenial, and the bushes be young, the berries of the black currant are frequently as large as small black cherries.

The Gooseberry.

This universally known shrub is a native of Britain, and easily cultivated; it is indeed so hardy, and suitable for even keen climates, that remarkably little fostering is required to keep it in perfection; but it will not succeed in warm countries, its latitudinal range being in reality very limited. After a long course of culture, there are now hundreds of varieties of gooseberries; still, the kinds which keep their place in public estimation are few in number. The following are some of the leading sorts:—*Reds:* Kean's seedling, Leigh's rifleman, Boardman's British crown, red Warrington. *Whites:* Taylor's bright Venus, Wellington's glory, Saunder's Cheshire lass, Woodward's whitesmith, Cook's white eagle. *Greens:* Parkinson's laurel, large smooth green, Collier's jolly angler, Massey's heart-of-oak, Edward's jolly tar. *Yellows:* Didon's golden yellow, Prophet's regulator, Prophet's rockwood, Brotherton's golden sovereign and pilot. The following are small, but of very good flavour:—*Reds:* red champagne, red Turkey, rough red, ironmonger, and Rob Roy. *Whites:* white champagne, white crystal, early white, and white honey. *Greens:* early green hairy, green gage, and green walnut. *Yellows:* yellow champagne and rumbullion. The small red sorts ought to be preferred for preserves.

Although the gooseberry can be grown in almost any garden-soil, yet if excellence of fruit is desired, the soil must be a rich loam, not less than twelve inches deep, and resting on a well-drained, yet cool subsoil. The plantation should not be shaded too much by trees; for if these intercept the light, the fruit will not be large, full coloured, or high flavoured. Whether to form an entirely new soil, or to improve that in which the plantation is to be made, the following compost, recommended by Mr Haynes, may be advantageously adopted: Of fresh or maiden earth, from a light loamy rich pasture, take one whole spit-deep, with all the turf; to which add one-fourth of rotten stable litter, preferring that from an old hotbed made in the previous spring, which, from its softness and greater readiness to intermix with new soil, will be found preferable to every other; add one-fourth of the finest soft and black bog earth, or, in default of this, either the same quantity of the darkest-coloured leaf or vegetable earth, preferring that from hard-wooded trees. Mix the whole regularly together, laying it into one narrow heap or ridge, about a yard high, in any situation exposed to the sun and air, there to remain for six, nine, or twelve months, as

circumstances may admit; turning over the whole every three weeks, when the weather is favourable. The longer the compost remains in this state, the more advantageous it will prove.

To propagate the gooseberry, take cuttings eight inches long, of the last spring's wood, having a small piece or heel of the older wood; they are inserted about the end of October, or in spring, to the depth of three inches. The situation should be shady, the earth rather sandy, and each cutting should be fixed firmly in the soil. It is customary to remove all the buds excepting four or five at the top, which are left to form the head, produced from one central stem. Should three or four eyes break at the upper part of a cutting, it will be desirable to remove all others lower on the stem, as soon as it shall be manifest, from the vigour of growth, that there are good and sufficient roots to support them. When the head is formed, gooseberry-bushes can be spurred as directed for currants, avoiding to shorten the leading branches; or at each pruning in February, a certain quantity of the last year's wood should be retained, and a corresponding portion of the two and three years' old wood cut out; thus, as it were, renewing the trees annually. Larger berries are thus obtained from strong young wood than by the spurring-system.

When the fruit has fully set, the smaller berries may be removed for tarts, and the fine berries left to ripen for dessert. If some of the reds, as the Warrington, and the thick-skinned yellows, as the Mogul, be matted over when the fruit is ripe, it will remain good till nearly Christmas.

The Raspberry.

The raspberry is a common native plant in Britain; but has been improved by culture. The choice sorts are 1. Red Antwerp, fruit large, of high flavour, ripe in July; but by being planted behind a north wall, can be retarded, and the season thus protracted some weeks. 2. Yellow Antwerp, light coloured, very bristly wood, of luxuriant growth; fruit admirable in flavour, luscious; peculiarly adapted for dessert. 3. New double-bearing, which is rather an autumnal raspberry than strictly a double bearer, still, by due and timely pruning, a second crop is frequently obtained in autumn.

The raspberry is propagated by suckers taken up from among those which rise in abundance around strong plants. The fruitful shoots or canes bear but once, and should always be cut down in August, to admit air and light to the young shoots of the summer; and from these suckers some should be selected to renew the stock every five or six years, changing the soil or situation. Care should also be taken to remove the disorderly suckers which rise from the wandering roots. The soil for this plant should be a light loam well manured; an occasional dressing of lime-rubbish produces fine canes and very fine fruit. The plants, if placed in rows, should stand a yard or four feet asunder. They may be supported by strong stakes; confining the bearing shoots to them, the successional shoots will rise, without interfering with the others.

Raspberries are by no means of difficult culture, and are often profitably grown in shaded situations, where scarcely any other crop can be raised. Thus we have seen excellent raspberries grown in a north border, entirely secluded by walls and trees from even the faintest ray of sunshine. The waste ground around cottages is sometimes occupied with advantage by this fruit, and in such situations the raspberry bears abundantly, without the least care or culture, if not exposed to the predatory visits of village children.

The Strawberry.

The strawberry is one of the few fruits indigenous to Britain, and is found, like the bilberry and juniper, in a wild state in uncultivated spots, chiefly in woods and on tangled shrubby banks. It is likewise found in all the other northern countries of Europe, particularly in Norway, among whose rocky mountains it grows in great abundance; it prevails also in the temperate regions of South America, and abounds in the colder climate of Canada and Nova Scotia. This delicious small fruit is, in short, very generally scattered over the earth, and was the delight of ancient as well as modern times. In Latin, its name is *Fragaria*, which is supposed to be significant of its fragrance.

The strawberry is one of those plants to which nature has given the means of extensive multiplication. From the main stem there spread forth trailing suckers over the surface of the ground, and these fastening themselves by a root at every joint, as many new plants spring up as there are joints. A single tuft will, in this manner, if not kept within bounds, soon spread over a moderately sized garden.

In most parts of England strawberries are eaten alone, or dipped individually in sugar before being put into the mouth; and to suit this mode of consumption, they are brought to table with their stalks attached, which form shanks to hold by. But in Scotland they are consumed in a far more wholesale manner. There they are brought to table stripped of their stalks, and are ladled out and eaten with a plenteous infusion of cream and sugar. 'Strawberries and cream' is, in fact, one of the grand national treats which strangers may reckon upon seeing set before them in the early weeks of July, and to which generally full justice is done. In the neighbourhood of the large towns in Scotland there are many market-gardens deriving celebrity from their extensive strawberry-grounds, and to these, parties proceed from town to enjoy the fruit in perfection; that is to say, along with the richest and most delicious cream. In the vicinity of Dublin, the celebrated 'Strawberry Beds' in the same manner attract immense crowds of persons in the summer evenings, when the fruit is in its prime.

It is only in the neighbourhood of London that the successive cropping of strawberries, or the forcing of them at particular seasons, is methodically conducted on a large scale. In most parts of the country, the vicinity of Edinburgh included, the fruit in its different varieties comes almost at once into the market, the season lasting about three weeks, and then all is over. The exceeding precariousness of the crop, from the liability to damage from rains, makes the rearing of strawberries a business of uncertain profit.

After many years of observation and experience, Dr Neill recommended the following selection of sorts. Those most worthy of cultivation in small gardens are distinguished by an asterisk:

* Old Scarlet, or Virginian.	* Old Pine, or Carolina.
* Grove-end Scarlet.	Wilmot's Superb.
* Kean's Seedling.	Myatt's Pine.
* Roseberry.	* " British Queen.
Downton.	* Large Flat Hautbois.
* Knevett's.	* Prolific Hautbois.
* Elton.	Alpine, red and white (for preserving).
American Scarlet.	Wood, red and white (for preserving).
Coul Late Scarlet.	
* Princess Alice.	

The following comprehend the general directions for culture: The seasons for planting are March or September. The soil that all affect is a rich firm loam, trenched to the depth of two feet. The best and strongest-rooted runners are always to be preferred; and these should be planted at the periods above named, into beds or borders recently prepared. Many persons retain their beds or rows, during an indefinite number of years, in a tolerable state of fertility; but the triennial system appears to combine every advantage, while it avoids the two extremes of annual renewals and of protracted duration. When a bed is formed and in full bearing, it will require an annual surface-dressing of loam and manure, two parts of the former to one of the latter, early in the winter, to protect the plants and receive the new roots, which always are emitted just

below the lowest leaf-stalks. In March, the old leaves ought to be all cut off, leaving the hearts untouched; and the beds should be cleared of litter by a wooden rake. Prior to the fruit becoming ripe, the mowings of a lawn or of any soft grass or straw laid over the surface of the soil, will prevent the berries from being soiled.

Triennial System of Planting.—1. A plot or border of earth being trenched, as before directed, select, after the first rains of September, a quantity of strong and well-rooted runner-plants, and with a garden fork or trowel, set them one by one, fresh from bed, in the new ground; if in single border row, a foot apart; if in a bed, at the same distance plant from plant, but the rows two feet asunder. Fix each plant firmly, and give water over it from the rose of a watering-pot. If a set of plants be thus merely transferred without much disturbance, and watered, few will fail. Hoe the ground occasionally; and prior to or during the first frost, sprinkle some manure over and around the plants. Suffer no blossom to expand in the following spring, but leave the plants to acquire strength. Stir the ground occasionally, and cut off all runners.

2. In the second September, prepare and complete a corresponding plantation. Manure and dress the plants during winter, and those of No. 1 for the second time; and in March trim off the old leaves, and rake the surface. Let the plants of No. 1 bear their full complement, the fruit of which ought to be early, abundant, and of first-rate quality.

3. In September of the third year, repeat the work, and thus complete the plantations. Treat this and No. 2 exactly as directed for No. 1. In the following spring, suffer No. 1 to bear a second crop, No. 2 its first crop, and obliterate the blossoms of No. 3. In the September of the fourth year, dig up all the plants of No. 1, turn the ground, manure, and replant it. Thus the routine will be completed; and thus, year after year, there will be a plot progressing in one of the three stages; and if, with each approved variety, a similar routine course be adopted—and especially if a plantation be formed in the three aspects, east, south, and north, the last under a hedge or fence, to screen it from the south sun—the season of strawberries can be extended between the latter end of May and the middle of August. For the latter period, Knight's Elton is peculiarly adapted; and they who can at that time command a supply of a fruit so fine and beautiful, will have ample cause for self-congratulation.

The Cranberry.

The common cranberry (*Oxycoccus palustris*) grows wild in upland marshes and turf-bogs both in England and Scotland, and generally over the northern parts of Europe. It is a trailing-plant, with slender shrubby shoots, which are clothed with small linear leaves; the fruit is an austere red berry, about the size of the common currant. It flourishes by the sides of little mossy rills, but not among stagnant water; hence the difficulty of making it an article of culture. The American cranberry (*O. macrocarpus*) closely resembles the common species, but is a larger plant. Its fruit is also larger. Though growing wild in great abundance, it is a plant of easy culture; and in some parts of the United States, barren wastes, meadows, and coarse herbage are converted into profitable cranberry-fields at little expense. The plant grows well on sandy bogs; and if these are covered with brushwood, the bushes should be cleared away. Some cultivators plough the land previous to planting; the latter process being performed by digging holes, four feet distant each way, to receive the roots of the young plants. In three years, the whole ground is covered, and an acre in full bearing will often produce 200 bushels, which bring about one dollar per bushel.

The cultivation of the American cranberry in our own country was first recommended by Sir Joseph Banks; and several gardeners have been so successful in the attempt, that this berry may now be regarded as one of our cultivated fruits. 'Wherever there is a pond,' says Neill, 'the margin may, at a trifling expense, be fitted for the culture of this plant, and it will continue productive for many years. All that is necessary is, to drive in a few stakes, two or three feet from the margin of the pond, and to place some old boards within these, so as to prevent the soil of the cranberry-bed from falling into the water; then to lay a parcel of small stones or rubbish into the bottom, and over it peat or bog-earth, to the depth of about three inches above, and seven inches below, the usual surface of the water. In such a situation, the plants grow readily; and if a few be put in, they entirely cover the bed in a year or two, by means of their long runners, which take root at different points. From a very small space, a very large quantity of cranberries may be gathered; and they prove a remarkably regular crop, scarcely affected by the state of the weather, and not subject to the attacks of insects.' Although a moist situation is best suited to the plant, yet, with a due mixture of bog-earth, it will flourish, producing abundant crops, even in a comparatively dry soil.

The Grape Vine.

The vine (*Vitis vinifera*), from the juice of whose fruit wine is made by a process of fermentation, is a plant of Eastern origin, which, in the course of ages, has been introduced into all the countries of Southern and Central Europe. Requiring a fine climate, it will not bear fruit in the open air in most parts of Britain; and it is only in fine seasons, and in good exposures, that its fruit is worth eating, even in the southern parts; in general, the grapes grown in gardens about London are small, and not presentable at table. In the north of France and Germany, they are little better, and we do not really get fine grapes of a proper size till we reach Italy or Portugal. In England, however, grapes produced in hothouses surpass in size and flavour the fruit of the Portugal vines.

Throughout the continent, the practice is to grow vines in large fields, either on plains or the sides of hills, which are fully exposed to the sun. They are trained in rows, tied to stakes, and are pruned to a height of about four or five feet; on the Rhine, they seldom exceed three or four feet; and at a distance, the ground has somewhat the appearance of being covered with staked beans or peas. In Italy, the vines are trained to a greater height, and are made to cling to horizontal palings, as if from the roof of a hothouse.

To those in the southern parts of England, who desire to rear the vine in gardens and on walls, we offer the following directions: The varieties most suitable for culture are—1. The white sweet-water, with round berries, somewhat tinged with yellow, and faintly streaked with red on the sunny side. 2. The white muscadine; bunches rather loose, berries not very large, yellowish, and abounding with saccharine juice. 3. The small black cluster, with berries between red and purple, closely packed, very sweet, and luscious in flavour. 4. Turner's hardy, a fruitful tree, and very certain bearer; berries of medium size, varying from dark-red to deepish purple.

A sound turfy loam, to the depth of eighteen inches, rendered open by small fragments of old lime-rubbish and a portion of crushed bones, will support any vine, and promote its fertility; and these materials can be introduced by degrees, first near the roots, then at a greater distance, to replace a corresponding quantity of old soil; thus little expense will be incurred, and still less labour. But if a new border be contemplated, and outlay be not considered, it will of course be best to complete the work in the first instance.

Vines are propagated by single eyes, by cuttings, and

by layers, placed in pots when it is intended to remove the plants to borders or vineries. The soil should be a light, rich, sandy earth, or perfectly decayed manure and sand in equal parts; but they who wish to raise vines without loss of time, should plant cuttings taken from vines of known fertility, and of the yearling shoots which are themselves actually fruitful. Each should have three bold eyes on the young wood, and each should retain at its base a small piece of the previous year's wood. The season for planting is the month of March, and the method very simple. Dibble a hole from four to six inches in front of the wall or fence, deep enough to receive the entire cutting. Mix together equal parts of black leaf-mould and white sand; put in the hole enough of this to raise the bottom one inch, and ram it hard with a blunt stick; then insert the cutting, and hold it firm in the centre of the hole, while that is filled brimful with the compost, which is brought into still closer contact with the shoot by watering. Make the ground quite even, and its surface level with the uppermost bud, then cover the cutting with a small hand-glass. If the ground is kept moderately moist, not two cuttings in a dozen will fail. If more than one shoot break, and attain the height of five or six inches, the stronger only should be retained, slipping the other off below ground. This shoot must grow till its point become spindling, when it should be nipped back; and all future growth should be thus stopped above its lowest leaf, as also the laterals that appear during the growth of the main shoot. Great care must be taken to keep the vine regularly nailed and secured by soft and roomy ties, to prevent accident, and the danger of being snapped by the wind.

As the aspects suitable to the vine are confined between south-east and south-west, the cuttings, if not duly supplied with water, may be droughted and perish before they become completely furnished with roots; but when once established, the main shoot will grow rapidly, perhaps attaining the height of a common fence, and ripen their wood early. In the end of September, let each be cut down to an inch above the three lowest buds; mulch the ground around the stems and over the roots as winter approaches, and watch the spring progress of the eyes. If possible, obtain and secure two equal shoots; and if the wall or fence be from eight to ten feet high or more, lead these shoots horizontally right and left about six inches above the soil, and secure them by shreds and nails. If the wall be six feet or under, retain but one strong shoot, and train it perpendicularly. In September, cut back according to the strength: thus, if the wood of the single rod last mentioned measure from one-third to half an inch in thickness, and the eyes be full, and from four to six inches apart, cut the shoot at the top of the fence, removing also the remains of all laterals and tendrils. The two horizontals will perhaps be rather slighter, yet if they be fully ripe, and furnished with bold eyes, they may be left three or four feet long on each side of the short main stem, but all the buds on the under side of each must be cut away; mulch the ground as before, and in March following, carefully fork in the manure.

Bearing Condition of the Vine.—The fourth spring will find the vines in a fruitful state; but, previously, the trees prepared for a dwarf-fence should be so pruned as to retain but three horizontal branches on each side of the main stems, about eighteen inches asunder, the intermediate branches being cut back to their lowest bold eye beyond the stem. This eye is designed to produce a new shoot, to take the place of the bearing-shoot, which, after the fruit is taken, must be cut away. Thus the vine will henceforward produce, year by year, two systems of branches, one of which will comprise year-old bearing wood, the other a corresponding series of green wood, which will produce the fruit of the following year. This description would almost suffice to elucidate the habits of the vine; yet to leave no doubt on a subject which involves the entire theory of pruning, it will be understood that this tree bears its fruit solely upon the green shoots of the present year, which spring from the eyes of the pale-brown wood of the previous year. When, therefore, a vine is of age, and has acquired sufficient strength to support a crop of fruit, it will generally be wise to provide a new series of bearing-wood every year, because the fruit of new wood—in the white varieties particularly—is always superior. In this horizontal alternate system for low fences, each new branch may safely be permitted to extend itself at least two joints beyond its predecessor, always remembering to cut back, early in the autumn, to a short distance above a bold eye seated on perfectly ripe wood; for thus the tree will acquire strength and extent at the same time; and experience proves that, in ordinary circumstances, the fertility of a tree should be moderated, and kept below the supporting power.

The trees on the second system of training for high walls must be pruned in a similar manner, and upon corresponding principles. In the autumn of the third year, three out of four branches will be cut down to the lowest bold eye, and a few vertical shoots, from thirty inches to a yard apart, will remain; and these also must be pruned to a strong eye situated on mature wood. This system will furnish new bearing-wood every year, increasing in length as the power of the tree augments; while also the low horizontal stems will extend gradually in due proportion. At first, one, or at most two bunches, must be permitted to remain upon each upright branch. In the fifth season, a greater crop may be taken, always, however, remembering to restrict the fertility of the vine; for by so doing, its vegetating power will keep in the advance, till, in the end, the entire fence will be filled with vigorous branches, annually renewed, from which a very heavy crop may be gathered without tasking the vine in any degree that shall produce debility.

The spur-system of pruning back the bearing-shoot annually, may occasionally be adopted with black grapes, and not without advantage; yet the system of yearly renewal leaves the vine at the entire command of the pruner, and procures large clusters of fruit. The few remarks above offered enter little into minutiæ, but they elucidate general principles; and if applied practically, will, we believe, lead to improvement in grape-growing.

The fruit of the vine grows in clusters or bunches, as many, perhaps, as a hundred grapes in the bunch. It is not desirable that so many should cluster together, for when numerous, they are apt to be very small, and to be so compact in the mass, that those within do not ripen. Bunches with many grapes, therefore, should be thinned, by clipping out those of the smallest size, which will allow the others to grow to the proper dimensions. In very many instances, grapes grown on walls in gardens are spoiled by vermin, the interstices in the bunches being often filled with spiders' webs and insects of different kinds. All this is a result of carelessness in not keeping the walls clean, and thinning and otherwise attending to the bunches. As a preventive, let the walls in winter be lime-washed, including all branches of the vines, and take some pains to remove all vermin which appear in the fruit-season.

Forcing.—Of the growing of vines in hothouses or vineries, it is not our intention to speak; but for the class of persons whom we address, the following suggestive account of a method for forcing vines in humble edifices, given by Mr M'Intosh, in the *Orchard*, seems so suitable, that we take leave to offer it: 'In many parts of the continent, and even in some few instances in this country, vines are forced in very humble edifices. The Dutch, Flemings, and Germans use pits, often not exceeding three or four feet in depth. These are

sometimes heated by dung or tan being placed within them, which give out a mild, humid heat, serviceable to the vine while the buds are breaking; and this, with the proper husbanding of the solar heat by judicious ventilation, is often found sufficient to produce ripe grapes at an early period. Other instances occur of such pits being heated by a smoke-flue, to which very moderate fires are applied. But what is most novel in these pits is, the vines being planted outside—the wood that is to produce the fruit is trained under the glass within, while the young wood for succeeding crops is allowed to grow without, where, under a brighter sunshine than we enjoy, the wood becomes perfectly ripened; and when the crop is gathered, the old wood, or that which produced fruit this year, is entirely cut out, and replaced with the young wood hitherto growing without the pit. Vines are also ripened on the continent by having glass frames placed against the wall on which they grow, about the time the fruit is half or three parts swelled, at which period those glasses are not in use which have been employed in forcing early crops of melons, salads, &c. The solar heat collected by this contrivance ripens the fruit well, and fully matures the wood for the following season.'

Vine Diseases—Grape Blight.—The cultivation of vines under glass, although in the present day exhibiting highly successful results, has all along been attended with certain disadvantages, arising chiefly from the unnatural conditions to which the plants are necessarily subjected. Much has been written on vine-borders and on systems of pruning, and our horticultural literature is literally loaded with explanations of the causes of *shanking* and other failures of the grape-vine. Of late years, a new disease, known as the grape-blight, or vine-mildew, has made its appearance, and has proved very destructive to the crop. Unfortunately, this new disease is not confined to the hothouse, but becomes even more troublesome where grapes are grown in the open air. It has, in fact, become as great a scourge of the wine-countries as the potato disease has been to Ireland; and has served in many cases to change the course of industry, as, for example, at Teneriffe, where, according to Professor Piazzi Smyth, the vine is being displaced by the cochineal insect, which gives a more certain return. The grape-blight first manifested itself at Margate, in England, and gradually spread into France, appearing at Versailles in 1848, at Paris in 1849, and finally extending to the south of France in 1851; at the same time, it rapidly travelled the whole length of Italy, from the coast of Liguria to Naples; then, as autumn approached, taking a retrograde course through the Tyrol, as far as Botzen, overrunning nearly the whole of Switzerland northward to Winterthur, and at last trespassing on certain isolated points of Germany at the Hardgebirge, in Baden at Salem, and in Würtemberg at Stuttgart and Cannstadt (Hugo von Mohl). The disease seems in many cases to have made its first appearance on vines under glass, those in the open air becoming subsequently affected. According to Mohl, where vines are grown exclusively in the open air, those trained to walls suffer more than the vineyards in the open field. In many cases, the disease has been observed to pass from the trellises to the neighbouring vineyards. 'It reached the greatest height on those trellises which stand under the wide-spreading roofs of the Swiss houses.' Invariably the finest vines suffer most severely, and especially those that are carefully pruned and trained under shelter.

The diseased condition is accompanied by, and is apparently due to a minute fungus (*Oidium Tuckeri*), which consists of delicate cobweb-like threads, which spread over the surface of the young shoots, leaves, and fruit of the vine, decomposing its juices, and interrupting development of the tissues. The effect of the parasitic mould upon the fruit is most remarkable: the filaments referred to spread over the whole surface of the fruit, acting detrimentally upon its skin only; the soft fleshy interior goes on expanding in vigorous growth; but the infected skin, having lost its vigour, ceases to expand in proportion, so that the berry becomes ruptured, and either dries up or rots. In infected districts, whole bunches may be seen in this condition—the vine-twigs languishing, and left by the disheartened cultivator to be choked with weeds. We have had the opportunity of studying the disease in England; but have sought in vain for diseased vines in Scotland. It is not necessary that we should here consider whether the *Oidium Tuckeri* is a new and specifically distinct fungus, or merely an aberrant form of another known species. That question must still be regarded as quite an open one, especially since the experiments of Mr Lowe, detailed in a paper read to the Botanical Society on the 11th of June 1857, have shewn so many so-called species to be referrible to the *Aspergillus glaucus*, or common blue mould.

There is no *effectual* remedy applicable to extensive vineyards in the open air; but dusting with sulphur proves highly beneficial where the plantation is sufficiently small to permit of its being well done. In hot-houses, this remedy is of the greatest service, and ought to be resorted to in all cases where the disease makes its appearance.

The Fig.

The fig-tree is a delicate exotic like the grape-vine, and great care is required to bring crops of the fruit to maturity in the open air. There are many kinds of the fig-tree, but the greater number are adapted to culture under glass only.

In this country, the nomenclature of figs is very unsatisfactory; but the following list embraces most of those known in cultivation. The kinds best adapted for forcing are marked with an asterisk, the others being suitable for the open wall in warm sheltered situations. The fruit cannot, however, be depended upon except in favourable seasons:

* Black Ischia.	Pregussata.
Brown Ischia.	Lee's Perpetual.
Black Genoa.	* Early white.
Brunswick or Madonna.	* Marseilles or Figue blanche.
* Brown Turkey.	

The best soil for fig-trees is a light fresh loam; but the chief essential to promote fertility is a hard and dry bottom of chalk, gravel, or artificial pavement; a dry substratum, and little depth of soil—that is, from one foot to eighteen inches—are therefore what the gardener must provide, if he expects to render the trees permanently fruitful.

As to culture and training, both are extremely simple. Rogers says, and very justly, 'that the knife is seldom wanted' [that is, in shortening; though, from the extreme luxuriance of the wood, it is frequently necessary to cut out many entire shoots]; 'pinching off the points of the young shoots during the months of May and June with the thumb and finger is the most effectual pruning.' Mr Knight restricted himself to compressing the points of the green shoots till the substance was felt to yield under the finger and thumb, by which pressure a check is given to luxuriance.

To secure fruit in due season, the pruner must recollect that in Italy and the south of Europe two crops of figs are produced yearly. Those large figs which are seen on fruitful trees here late in summer, are developed in spring, and would ripen early in a warm climate; but our winters check their progress, and generally destroy them. The crop which ripens in August is developed late in the preceding summer, and is extremely minute, almost invisible, in September; these figs are situated near the terminations of those green shoots which have been pinched or compressed; therefore the large green figs should be displaced by

mid-August, and then it will frequently be seen that two minute fruits form in lieu of the one; and these, if the tree be protected, will ripen at the season mentioned. As to protection, it will be proper to unnail and bend down the upper shoots, so as to bring them into moderate compass, then to pass a few straw-bands among and across them, and finally to cover the whole with a mat or canvas sheet.

In April, train in, straight and regularly, all the bearing-wood; and as the trees grow, suffer the breast-wood to curve forward at its pleasure, pinching the points as directed. Not one shoot is to be cut shorter; but if the wood become redundant, branches which obscure the fruit should be removed, reserving those which will manifestly be fertile, and which can be duly trained in the following spring.

The Filbert.

The filbert is an improved variety of the common hazel-nut. Both plants are monœcious; that is, they produce male and fruitful blossoms very early in the year on the same tree, but separate from each other. As the trees are pruned—spurred, as it is termed—in autumn, care must be taken to reserve a number of catkins. The following are the methods of culture: Strong suckers, taken in autumn, are either planted in the nursery, or at once in the places where they are to remain; and these grow three or four years, and are then cut down within a few inches of the ground. From the stems, several strong shoots are produced, which, in the second year after cutting down, are generally shortened by one-third of their length. Regular figure and an open head are procured by training the branches. In the third year, as the bush approaches maturity, short shoots (spurs) spring from the eyes, and are suffered to grow till the autumn, when they are cut back nearly to their origin, whilst also the leading shoots of the previous year are shortened two-thirds.

In the following spring, several small shoots arise from the base of the small branches which were cut off the preceding autumn, in consequence of the curtailment of the leading trained branches, and upon these secondary spurs the fruit may be expected; these shoots augment in number yearly, insomuch that many must be cast away. The largest are removed; the lesser remain, being more fertile in their habit. Many decay yearly; but whether they do so or not, those which have borne filberts are always cut away, and a fresh succession provided as future bearers. The leading shoot is every year shortened two-thirds or more, if the tree be weak, and the whole height of the branches must not exceed six feet. In order to strengthen the tree as much as possible, the suckers of the roots are eradicated.

The crops thus produced are sometimes enormous, followed, however, by intervals of barrenness. We have not heretofore adopted the method of pruning, leaving the trees more to the order of nature; but it is right to try experiments; and when a row of young trees exists, a comparison might readily be obtained, by pruning alternate trees, or one of every three trees, by the 'spur-system;' always, however, observing to keep the head of every tree open, and to cut away its upright central leader.

The Mulberry.

The mulberry is a native of Italy, introduced in 1548. The structure of its flowers and fruit is very singular; like the nut and filbert, the males are distinct from the females; the latter do not always expand at the same time as the males, and therefore are not fertilised. The black mulberry thrives best in good loam; the bed ought to be deep, and to rest on a dry sandy subsoil. The fruit sometimes fails; and on this subject Rogers observes, that fertility may depend very much on the warmth of the weather at the time of blossoming, and on the circumstance of both male and female flowers coming forth at the same time; sometimes also the male catkins drop before the fruit-blossoms expand. Williams of Pitmaston suggests, 'that no tree receives more benefit from the spade and dunghill than the mulberry; it ought therefore to be frequently dug about the roots, and occasionally assisted with manure.' Others consider a velvety piece of turf as the best site. When the buds expand in the third spring, it is desirable to obtain four shoots on each side of the upright stem, and all the shoots that will break from the two horizontals, which latter are to be led upright, and secured as they advance.

The Melon.

The melon requires more care in cultivation than most amateur gardeners can bestow upon it; but of late years the introduction of heating by hot water for forcing purposes has largely displaced the old system of dung-heaps, and has simplified the management of melons, and rendered them a more certain crop. They are now usually grown in low, glazed pits, having pipes of hot water flowing beneath the bed of soil, to afford bottom-heat. The most recent system of culture is that given in the *Florist and Fruitist* for June 1857, from which some of the following hints are abridged: The trellis for training the melon-shoots should be eighteen inches from the glass, and the foliage should be kept six or seven inches from the glass, so as to permit a free circulation of air. The first sowing may be made at the end of November, the seeds being sown thinly in pans; the seedlings require great attention at this dull season; keep them near the light, and when they are sufficiently strong, prick them singly into pots, using pure loam. Early in January, prepare for planting. Melons succeed best in marly or clayey loam, and the soil must be made firm before planting, whether the plants are grown in the beds or in pots; the latter are preferred for the earliest crop. In the middle of January, the soil in the pots having become warm, the seedlings are to be planted, one in each pot. When the stem elongates, carefully tie each to a stick reaching from the pot to the trellis, and when trained along the trellis, stop them, by pinching out the point of the shoot, to induce fertility. Three fruits will be plenty to allow to swell off on each plant. Be careful to regulate the temperature, and to keep the atmosphere moist, watering the soil occasionally with liquid manure. The following are some of the best varieties in cultivation at the present time (1857): Bromhall, Victory of Bath, Egyptian Green-flesh, Orion, Beechwood, Trentham Hybrid.

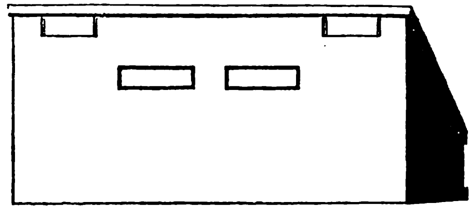
THE ORCHARD-HOUSE.

Of late years, an innovation has been made on gardening practices and prejudices, by the introduction of hardy fruit-trees to pot-culture. This may at first sight seem a refinement in horticultural art, which is not needed by those whom it is the chief object of these pages to instruct; but on closer examination, it will be found that the orchard-house, or, as its author, Mr Rivers, prefers to call it, the 'glass-roofed shed,' does not so much belong to the professional gardener as to the amateur and the cottager, and especially to the tenant of a town-garden. It is described as a place requiring but little expense to erect, but little experience and attention to manage, and yet giving pleasing results to the suburban gardener, who has but a small garden—which must be a *multum in parvo*—to the amateur with plenty of gardening taste, and but a limited income; in short, to a numerous class, with minds full of refinement and capabilities of enjoyment of horticultural pleasures, but with purses not so bountifully supplied.

The principal object of these orchard-houses is to grow small apple and pear trees, cherries, &c., in pots, to greater perfection than can be done in the open

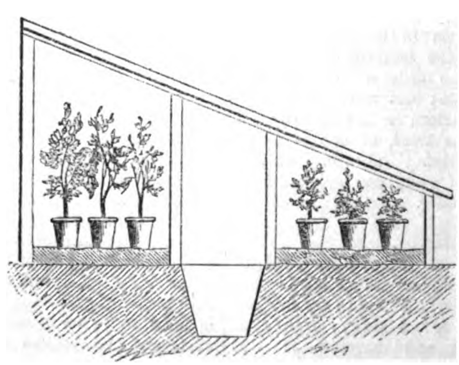
ground, as well as to obtain grapes, &c., without the expense of vineries. By the peculiar management adopted by Mr Rivers, which shall be explained, a crop of fruit may be realised in course of a year or two after planting, and this is a great point, inasmuch as it enables the amateur to reap a speedy harvest; for it has long been a standing adage in gardening, that 'those who plant pears plant for their heirs.'

Mr Rivers thus describes his 'glass-roofed sheds:' Their length may be from ten feet to one hundred or more, according to means and space; but their breadth and height must be according to the following dimensions: Suppose the structure is to be thirty feet long; a ground-plan, thirty feet long and twelve wide, must be marked out; then ten posts or studs of oak or good yellow deal, four inches by three, and nine feet in length, must be fixed two feet in the ground firmly, the ground-ends being previously charred to the extent of two feet four inches from the bottom: this back-line of studs will thus stand seven feet in height clear from the surface. For the front-wall, ten studs four feet long must be inserted 1½ feet in the ground, so that they stand two feet six inches clear from the surface: on these studs, both at front and back, must be nailed a plate four inches by 2½ inches, on which the rafters are to rest: the studs are thus far arranged into two lines. The rafters are fourteen feet long, and four by two inches in thickness, placed with the narrow surface upwards. To spare the trouble of 'ploughing,' to make the rebate for the glass, which is great labour and waste of material, a slip of ½-inch board, ⅞ths of an inch wide, is nailed on the upper side of each rafter exactly in the centre; this will leave ⅝ths of an inch on each side for the glass to rest on—not too much for glass twenty inches wide. The rafters are now fitted on the plates at top and bottom; they must never be mortised, but let in at top by cutting out a piece, and sloped off at bottom. To receive the glass at the top of the rafters, a piece of ¾-inch deal-board, six inches wide, must be nailed along the top to the end of each rafter, so as to be even with the surface, and in this should be a groove to receive the upper end of each piece of glass; at the bottom, a piece of board, one inch thick and six inches wide, must be let in for the glass to rest on, and to carry off the water. We have thus a sloping roof seven feet three inches high at back, and two feet nine inches in front. The glass used is 16-oz. British sheet, costing about 2½d. to 3d. per foot, and the best size of pane is twenty by twelve inches, the panes being placed crosswise, so that the rafters must be about twenty inches asunder. On and outside the back-studs, ½-inch boards must be nailed, well-seasoned, so that they do not shrink too much, and painted white or stone colour. In the back-wall, sliding shutters, 2½ feet by one foot, in grooves, must be formed for complete ventilation—two close to the roof, and two about eighteen inches from it, as in the annexed sketch.



Back of Orchard-house.

The front has also ½-inch boards nailed on outside the studs; one of them—the upper one—to be on hinges, so as to let down; and thus air is given throughout the whole length of the house. The *building* is now completed; but its low dimensions do not admit the builder. It is therefore necessary to form a footpath by making a trench 2½ feet wide and two feet deep in the centre of the ground-plan, which will leave a raised border on either side, four feet nine inches wide; the sides of the border may be supported by boards or brickwork. The border is to be made loose and open by a mixture of cinders, lime-rubbish, broken bricks, &c., and is enriched by manure. The pots containing the tiny fruit-trees are placed on the surface of the borders, and the foliage is thus near the glass. The roots make their way through the apertures in the bottom of the pots, which are enlarged for that purpose, and the plants thus, even in small pots, attain enough of vigour to support a crop of fruit. After the fruit is gathered, the pots are raised slightly on one side, and the protruding roots cut off with a knife; and the plants soon go to rest for the winter. It will be seen that the principle is to permit the plant to feed in the rich border by means of its protruded roots while the fruit is being matured, while any tendency to luxuriance is checked by the removal of these roots in autumn. The trees are thus kept of convenient size and in a very healthy bearing condition. Trees adapted for this method are kept for sale in pots in all the larger nurseries; and for ample details of cultivating the different sorts, we would refer to Mr Rivers's pamphlet. This system renders the fruit-trees portable; and such trees now occasionally appear at horticultural exhibitions, while they also present a novel feature in the dessert. 'What can be more gratifying than bushes of Moor-park or peach apricots, studded with their golden fruit, arranged on the sideboard of the dining-room, or the same of peaches, nectarines, plums, cherries, and grapes?'



Section of Orchard House.

A Pine Forest.

ARBORICULTURE.

CULTIVATION is so intimately associated in our minds with an annual, or more frequent stirring of the soil, that the term ARBORICULTURE—the cultivation of forest-trees—would at first sight almost seem to imply a paradox. We are so accustomed to see trees growing in extensive forests, on the bleak hillsides and in rocky valleys, whose soil and climate are incapable of supporting the ordinary races of cultivated plants, that we are prone to adopt the notion that trees grow out of the old turf of their own accord, and can be none the better of any care or attention on the part of man. Various writers have from time to time endeavoured to contradict this popular fallacy, and to shew that forest-trees require as much care and attention as any other cultivated crop. Such views have not as yet, however, been universally adopted by landed proprietors and others whose interests are concerned; but there can be no question that they are daily gaining ground, and will erelong effect important changes in the arboriculture of the British Islands. The rapid advances which have been made in the two sister-branches of rural economy, Agriculture and Horticulture, within the present century, hold out hopes that Arboriculture, which has now begun to follow their footsteps, will soon present an aspect very different from that which it has so long exhibited as a mere empirical art. Geology, Vegetable Physiology, Botany, and Entomology, all have important bearings on Arboriculture, and upon these it ought to be founded. It is a branch of industry upon which our national prosperity very much depends; and happily much improvement has of late years been effected in the management of our royal forests, which, if Blue Books speak truly, have met with an amount of neglect which contrasts strongly with the importance of our naval force. This is not to be wondered at, seeing that private properties of the same kind have in many instances been allowed to grow on and decay, without attention or control, until a pressure of debt on the proprietor, or some other untoward event, has led to an investigation of all available sources of income; and then, in most cases, a total clearing of the forests has taken place for the sake of their marketable timber, without any consideration as to the possibility of an increase of ultimate revenue from partial thinning or other steps of judicious management.

Mr James Brown, in the *Transactions of the Scottish Arboricultural Society*, says: 'Arboriculture is a much more difficult subject to deal with than either farming or gardening, inasmuch as a greater length of time is necessary to develop improvements and conduct them to a profitable issue. Hence the reason that the cultivation of trees on sound principles has hitherto been so very much neglected, and consequently that their culture as a crop has generally been attended with unsatisfactory pecuniary results. Instances, however, are by no means wanting in which this branch of rural economy has been conducted on sound principles, and in all such it is invariably found to be highly productive of profit to the proprietors, both directly by the proceeds of its produce, and indirectly by the shelter produced, and the consequent enhancing of the value of arable land. Such examples freely justify the expectation that, were all plantations cultivated on like principles according to their kind, pretty nearly the same results would in all cases follow. But although many instances of well-managed plantations could be indicated, and of such

results naturally occurring, still I believe that every intelligent forester will agree with me that this happy condition of things in respect to arboriculture is of comparatively limited extent, and that at least two-thirds of the plantations in Great Britain are at the present time either almost entirely neglected, or so dealt with that their condition is hopeless, whether as a profitable or an ornamental crop. This assertion may to some appear overstrained and beyond the truth, but it is based upon my own experience in surveying woods in all parts of the country during the last ten years. In England, I have seen oak-plantations of nearly thirty years' standing, with the trees in them only from four to five feet apart. From never having received the slightest attention as to thinning, the crop, as might have been expected, consisted of mere poles. This is an average illustration of the degree of knowledge exercised with regard to the rearing of timber in many parts of England, and it is scarcely to be wondered that profitable results do not follow such management. In Scotland, too, I have found a considerable extent of plantations which had never been thinned, although nearly thirty-five years of age. In these I found the trees averaging only about four feet apart; and of course, in such a condition of crowdedness, they were so slender that to attempt thinning or improving them was hopeless. Such examples are sufficient to shew that there is very great room for improvement in arboriculture both in England and Scotland.'

STRUCTURE AND PHYSIOLOGY OF TREES.

The general structure and physiology of plants have been explained under VEGETABLE PHYSIOLOGY and SYSTEMATIC BOTANY, to which reference may be made. The *stem*, which chiefly concerns our present subject, presents an infinite variety of modifications—assuming the form of a globular or columnar mass, as in cacti; or a pseudo-bulb, as in orchids; a hollow-jointed culm, as in grasses; a lofty branchless caudex, as in palms; or it may be twisted in a spiral manner around other plants, or form an underground rhizome, or an upright branching woody trunk, such as we see in our ordinary forest-trees. But all modifications of the stem are reducible to three well-marked forms, which differ not only in their mode of growth, but also sufficiently so in outward appearance as to render them easy of recognition. The three forms of stem are these:

1. *The Exogenous*, or *Outward-growing Stem*, which, in its growth, increases indefinitely in an outward direction by the annual formation of new layers of woody matter formed on the outside of the preceding layers, but inside the bark. This kind of stem is therefore an 'outward grower,' its thickness being yearly increased by the addition of successive concentric layers of wood.

2. *The Endogenous*, or *Inward-growing Stem*, whose increase takes place by the formation of new tissues towards the centre, so that the stem increases in thickness by the newly formed woody matter pushing out that previously formed, and not by the addition of new layers to the circumference.

3. *The Acrogenous Stem*, in which the increase takes place at the summit only, by the union of the bases of the leaves. It is, therefore, a summit-grower.

These three modifications of stems accord with other important structural peculiarities. All plants having *exogenous* stems have also an embryo with two cotyledons, or seed-leaves, and their proper leaves have usually a reticulated or netted venation; all those having *endogenous* stems have an embryo with one cotyledon, and their leaves usually have parallel venation; and all *acrogenous* plants have no proper seed containing an embryo, being propagated by unicellular bodies called spores.

All these three classes include a certain number of *woody* stems—that is, stems whose tissue is sufficiently dense to form timber; but that of acrogenous stems (tree-ferns, &c.) is not profitably available for this purpose. Our timber-trees are therefore, in practice, reduced to the first and second classes. But we further find that endogenous stems, in their woody form (palms, &c.), are confined to warm regions of the globe, so that these also do not concern the British forester. On the other hand, woody exogenous stems are common in all northern countries, and to this class belong all our timber-trees in the British Islands.

In common language, the trunk is often named the *bole*; and it is this part which affords the timber for which most trees are reared. The trunk, and also the branches, are covered with *bark*, consisting of a series of thin layers; while on the outside of all is a very thin layer of a different substance, called the *epidermis*, or cuticle. The inner layer of bark receives the name of *liber*; it was on this substance that the ancients, before the invention of printing, were accustomed to write; and *liber*, it is well known, is the Latin word for a book. Within the bark is the wood, consisting chiefly of wood-cells or tubes and vascular tissues, closely interlaced. In the centre of the trunk is a small space filled with a soft substance called *pith*, from which proceed the medullary rays.

The growth of a true exogenous bole is as follows: The stem of a seedling consists at first only of cellular tissue, surrounded by an epidermis; but as soon as the leaves have expanded, some bundles of woody fibre are deposited, so as to have the appearance, in cross-section, of a dotted circle just within the skin. As the tree advances in growth, the cellular tissue in the centre becomes the pith, and rays of cells, forming the medullary rays, extend to the epidermis between the bundles of woody fibre. A membrane, or rather layer of vascular tissue, then forms round the pith or *medulla*, so as to separate it from the bundles of woody fibre, and the pith, in some cases, takes the form of a star with rays diverging from a centre. In the second year of a tree's life, the rays and the central pith both contract as fresh layers of woody fibre are deposited, and they continue to do so every year till the tree is full grown. This process of growth of the stem by concentric layers of woody matter is continued every year, and as the vascular tissue has always a different appearance from the tissue of the wood, the rings of vessels between the layers of wood, which are called *concentric circles*, and the medullary rays diminished to fine lines, may be always traced in a section of the trunk of a tree. The medullary rays become changed in time into thin hard plates, which still radiate from the centre to the outer circumference of the tree, and form what is called by carpenters the *silver grain* of wood. The central pith, in the meantime, has diminished to a mere speck in the middle of the tree. The newly deposited layer of wood appears soft and white for the first year, and is called the *sap-wood*. The inner layers form what is called the *heart-wood* or *duramen*, which is extremely hard and durable. As the layers of wood are thus distinct, and as one is generally deposited in temperate climates every year, it has been supposed that the age of a tree might be found by counting the number of concentric circles; but this rule does not always hold good, for the reasons hereafter explained. The sap-wood of regularly formed wood is usually white; but the heart-wood in many cases changes its colour to brown of various shades, dark red, or even black, according to the character of the tree. The *branches* precisely resemble the trunk in every feature of structure.

It will thus be seen that the trunk of a tree—of the exogenous kind—consists of a number of cylinders enclosing one another like so many layers or concentric circles disposed around an axis; and that, as a circular layer is deposited every year, it is possible to some extent to ascertain the age of the tree by counting the number of the layers. Decandolle observes that this method of reckoning is not liable to much error, but the inspection must be conducted with the greatest care, for

the older circles become condensed into a mass, and their number can only be guessed at by measurement. His plan is as follows: 'When I have got a section of an old tree, on which I can see the circles, I place a sheet of paper upon it, extending from the centre to the circumference. On this paper I mark every circle, shewing also the situation of the pith, the bark, the name of the tree, the country where it grew, and any other necessary observations. I also mark in a stronger manner the lines which indicate every *ten years*, and thus I measure their growth at *ten years'* intervals. Measuring from centre to circumference gives me the circles; doubling this, I have the diameter; and multiplying by six, I have the circumference.' He then presents a table of the periods of increase in the diameter of various trees, an inspection of which proves that every tree, after having grown rapidly when young, seems at a certain age to take a regular march of growth, and also that as trees advance in age, they still continue to form layers as thick as they previously did subsequently to the period of rapid growth. If such tables were multiplied to a sufficient extent, they would form data from which, by ascertaining the circumference of a tree, its age might be known without having recourse to the destructive process of cutting deep into the growing timber. 'If,' says our author, 'one cannot get a transverse section of a trunk, then one must seek for old specimens of each kind, the date of whose planting is known, measure their circumference, deduce their average growth, and calculate from them the age of other trees of the same kind, always keeping in mind that young trees grow faster than old ones.' Decandolle cites numerous instances of trees whose ages have been ascertained according to the rule here laid down. Some of these appear to be many centuries, if not thousands of years old; and what is remarkable, still exhibit symptoms of verdure and vitality. Such calculations are apt, however, to lead to very erroneous results when applied to trees grown in warm climates; and even in Europe the greatest caution is required.

The fact that trees of such vast age continue to bear foliage and fruit, affords indubitable proof of a very remarkable circumstance connected with the vegetable kingdom. In man and all other animals, we find an organisation, and a process of life going on, which are destined to cease at a certain period. But it is otherwise with trees. They appear to possess the power of growing on for ever without exhibiting any symptoms of decay, unless from accidental or extraneous causes. 'As there is formed every year a ligneous deposit, and generally new organs, there is not among the vegetable creation place for that hardness or rigidity, that obstruction of old and permanent organs, which constitute properly the *death from age*, and, consequently, that being the case, trees can only die from accidental causes. Trees do not die from age, in the true sense of the word: they have no fixed period of existence; and, consequently, some may be found that have arrived at an extraordinary age.' But although a tree thus possesses in itself the elements of continual strength and youth, numerous causes step in to interrupt or destroy its existence; so that we are not to be surprised if the number of such vegetable patriarchs should prove exceedingly small, compared with the immense extent of the earth's surface which is covered with forest-growth.

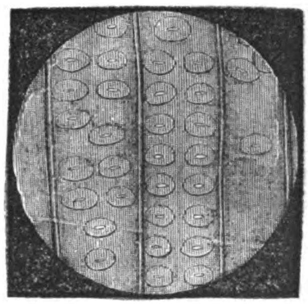
CLASSIFICATION OF TREES.

In arboriculture, trees are sometimes classified according to their uses; for example—1. Trees which produce straight timber for masts and long planks—as the various tribes of pines. 2. Trees which afford crooked timber for knees or bends in the ribs of ships, &c.—as the oak, sweet chestnut, broad-leaved elm, &c. 3. Trees which give tough pieces of timber—as the yew, holly, thorn, ash, hickory, maple, laburnum, &c. 4. Hard-wood trees—as the oak, beech, plane, walnut, box, and holly. 5. Soft-wood trees—as the poplar, large willow, lime, horse-chestnut, &c. 6. Wood or spray grown for hoops, baskets, besoms, poles, &c.—as the dwarf willows and birch. To these may be added woods of foreign growth—as rose-wood, satin-wood, and mahogany, which are employed for ornamental purposes.

According to another classification, trees are arranged as of three kinds—coniferous or resinous, hard-wooded, and soft-wooded. For the sake of clearness, we will adopt this simple arrangement, confining ourselves to trees which may be grown in the climate of Britain.

Coniferous Trees.

The obvious distinction of these trees is the production of cones containing their seeds; but they present other peculiarities. Their stems are usually tall and straight, bearing symmetrically arranged side-branches; and the wood-cells or wood-fibres, of which their timber is composed, exhibit under the microscope peculiar discs with a central dot—as shewn in the accompanying



Coniferous Tissue of *Wellingtonia gigantea* (280 diameters).

figure—which at all times serve to distinguish coniferous timber from that of all other families of plants, whether fossil or recent, even in a charred state.

The Coniferæ are not only useful timber-trees, but are also highly ornamental, their lofty trunks and pendent branches, clothed with peculiar evergreen foliage, rendering them conspicuous and pleasing objects in the landscape, either when grown singly or in groups or plantations. On this account, the Coniferæ have of late years received much attention from those interested in the improvement of estates; while the constant succession of new and useful additions that have recently been made to the lists of species suitable for our climate, has served to heighten the interest of this family of trees. The growth of Coniferæ has, in fact, assumed among the landed proprietors of the British Islands an aspect somewhat similar to the tulip-mania which rendered the Dutch florists so notorious; but there is one difference which we wish to keep in view in drawing this comparison—that while the Dutchman's 'fancy' only served to gratify a conventional taste, and to increase his fondness for gambling, the coniferous fancy, on the other hand, is doing good service to our country, in so far as it is yearly enabling us to grow more and better timber than was ever grown before in the British Islands. Keeping this fact in view, we can understand the reasons that actuate a proprietor in paying fifty guineas for a fir-cone: the timber which he may rear from the seeds it contains, is likely to give but a very inadequate return for such outlay; but he sees that future generations will reap the benefit of every really useful addition that is made to the timber-trees of Britain; and he deserves our best thanks for his generous devotion to our national prosperity.

Scots Fir (*Pinus sylvestris*).—This is a tall and generally straight tree, with few branches on the lower part of the stem, the foliage being confined to the top

of the plant, and there forming a massive clump. The numerous uses to which pine-timber is applied in this and other countries are well known. The Scots pine is indigenous to the northern parts of Europe and Western Asia, and forms vast natural forests in the Highlands of Scotland. It grows in almost any soil,

Scots Fir (*Pinus sylvestris*).

provided there be not a superabundance of moisture, and is justly valued as one of our most useful timber-trees. The two leading varieties are—1. The red-wooded or native; and 2. The white-wood, Haguenau, or continental Scots fir. Both are extensively grown; but a preference is usually given to the native sort, and especially to young trees grown from seeds saved in the indigenous forests of Scotland. Mr Brown gives judicious instructions for the growth of this tree, when he says: 'The best timber-trees for general purposes are raised where they are standing pretty close in one mass; but the tree assumes its most picturesque form when standing singly, with room to spread out its branches. When grown in one mass close together, the trees are found clean-stemmed, and drawn up to a great height; consequently such trees are available for many purposes; whereas, when standing singly, the tree is generally short-stemmed, thick, and branchy. No tree, a native of Britain, can with more safety be planted out into any soil and situation, provided only that soil be a dry one. I have seen a crop of good Scots fir taken off almost every sort of soil of an earthy or stony nature, but upon a mossy soil I have never seen good Scots fir timber grow.'

The Scots fir succeeds remarkably well in many of the northern parts of Scotland; but in the south, and especially in England, it is grown chiefly as a nurse to hard-wood trees, for which purpose its hardiness and rapid growth render it very suitable.

Weymouth Pine (*Pinus Strobus*).—The Weymouth pine produces a whitish-yellow wood, which is pretty hard, fine-grained, and easily worked; and being usually straight, this timber is much used for masts, bowsprits, &c. Lord Weymouth was the first proprietor who planted this tree extensively in Britain. It accommodates itself to most kinds of soils, but attains greatest perfection in valleys and on river-banks, where there is an accumulation of vegetable matter; so situated, it attains a height of from 150 to 200 feet, with a girth of stem of from 12 to 16 feet.

Corsican Pine (*Pinus Laricio*).—This tree yields a whitish resinous timber, darker towards the pith; it is coarse-grained, but easily worked, elastic, and durable, and is much used by the French in ship-building. In this country, it is not only a valuable timber-tree, but also a useful one for ornament, for it grows rapidly, and soon assumes a handsome pyramidal form. On a good light soil, it attains a height of from 100 to 130 feet, reaching maturity in the course of seventy or eighty years. It is a native of the south of Europe, chiefly occurring on high elevations; on Mount Etna, it grows between 4000 and 6000 feet above the sea-level, attracting attention by its huge, far-stretching roots, which creep over the rocks, and are exposed above the surface wherever the soil is shallow.

The 'Black Austrian Pine' is a variety of the Corsican Pine, having a flat spreading head. It appears to have even a greater adaptability for different soils than the normal form of the species; and the wood, which is very resinous, is much valued from its capability of resisting the effects of water, and of alternate moisture and dryness, which is even more trying for timber than constant immersion in water. So highly is this tree esteemed by many, that it is thought it may ultimately supersede the Scots fir; but the higher price of young plants has hitherto acted in some measure as a check upon its universal diffusion.

Cluster Pine (*Pinus Pinaster*).—This tree affords a soft, and not very durable wood, which is chiefly employed in making boxes, &c., and is better known in France than with us. The cluster pine, however, has strong claims upon our attention, for it is capable of producing timber on soils unfit for other plants. It is a southern European species, growing along the shores of the Mediterranean, and on the Apennines, to about 2800 feet above the sea-level. On wet soils, it will not grow; but wherever the soil is dry, even if exposed to the sea-breeze, it forms a handsome pyramidal tree, fifty or sixty feet in height. In France, it has been employed profitably to cover immense tracts of sand along the shore; and so far as it has been tried in similar situations in Britain, it has succeeded equally well. Resin is extracted by slicing the bark; and tar and lamp-black are obtained by burning the wood.

Spruce Firs constitute a well-known genus (*Abies*) of the Coniferæ, the more common being the Norway spruce (*A. excelsa*), a tree which attains great height, and furnishes white deal and spars; it is also very suitable for masts and poles of all kinds. The Norway spruce is now widely planted throughout Britain, particularly in the Lowlands of Scotland; and when enjoying a favourable situation, soon grows to a useful size. It is a hardy tree, and though its timber is softer and less durable than the Scots pine, yet, from the rapidity with which it grows, and its adaptation to a soil rather damp, it is frequently preferred.

In many parts of Northern Europe, it forms the principal timber; being known in the market as white deal or Christiania deal. When grown singly in a moist soil, the Norway spruce assumes a very handsome appearance, but it loses its beauty when grown in crowded plantations.

The *White Spruce* (*Abies alba*) is a North American species, whose root-fibres macerated, are used by the Canadian Indians as thread to sew their birch-bark canoes. It is associated with the *Black Spruce* (*A. nigra*), which is even a hardier species, growing in the most inclement regions. Its timber is very strong, light, and elastic, and is valuable for the yards of ships, and other purposes in which these qualities are required. The young branches yield essence of spruce, known to voyagers as an antiscorbutic.

Douglas's Fir (*Abies Douglasii*) is one of the most valuable of the numerous species introduced by that devoted traveller. It grows rapidly, but forms compact, heavy timber. It forms immense forests in

North-west America from 43° to 52° north latitude; the erect tapering trunks varying from 100 to 180 feet in height, and many of them nearly ten feet in girth. The bark of the young branches is swelled into globular receptacles of turpentine, and the wood-cells exhibit spiral fibres. The tree being very ornamental, and well adapted to our climate, is much sought after by cultivators, and is gradually superseding the larch, not being liable to disease. *Menzies' Fir* also produces timber of excellent quality.

The *Silver Fir*, called also the Pitch Fir (*Picea pectinata*), displays a greater depth of branches than the other firs, and becomes a majestic tree on arriving at full age. In this country, the silver firs are chiefly seen as objects of ornament on dressed ground. The quality of the silver-fir timber of British growth is rather indifferent. *Abies nobilis* is a magnificent tree, and many other species of the genus are in cultivation; such as the Indian, the Hemlock, Webb's, and the Balm of Gilead Fir.

The *Larch*.—Of this valuable genus (*Larix*) there are several species grown in Britain and other countries; the more common is the *L. Europœa*. The larch is one of the most beautiful of this class of trees; its straight elegant stem tapering to a point, and furnished with pendulous branches, which are ornamented with delicate drooping spray. It is of rapid growth; in many parts of the country, it has gradually superseded the common fir, over which it possesses a great superiority in point of ornamental effect; but of late years, the 'dry rot in larch' (as it is called) has served to discountenance its use for many purposes. 'There are,' says the authority already quoted, 'two varieties of the larch generally cultivated in Britain—the white and the red. The white is the variety which attains the greatest dimensions of timber, and is the sort most generally cultivated, although they are both often seen growing together in the same plantation, and that by mere accident. It is said that upon the Athol estates the red larch does not contain above one-third the cubic contents of timber which the white larch of the same age does; and this is observable in every plantation where the two varieties are found growing together. No timber-tree at present cultivated in our woods begins to repay the expense of culture so soon as the larch does. It is a rapid-growing tree, and is well adapted for almost every country purpose. It generally sells at nearly double the price per cubic foot that Scots fir brings; and besides the price of the wood, the bark is available for tanning. The circumstances which are found favourable to the healthy development of the larch are—as to soil it is not particular, but the roots must have a constant supply of water, in order to keep the earth in which they grow in a pure state, as is the case upon all rugged mountain-slopes where there is a continual descent of water from the higher ground to the lower.' On very arid soils, the larch never grows freely, and soon dies off with a stunted lichen-clad bole; and on flat ground, where water is liable to stagnate, though the young trees may succeed for a few years, yet they are never found to prosper, but die away as soon as the mere surface-turf is exhausted.

The *Cedar of Lebanon* (*Cedrus Libani*) is remarkable for its long horizontal branches, and the great mass of dark-green spicular foliage with which it is covered. It is a native of the mountains of Libanus and other high adjacent regions, where it attains great bulk, and grows to a very great age. From its solemn aspect, it forms a suitable accompaniment to ecclesiastical buildings or cemeteries, and also for sequestered glens in mountain scenery; it is equally well adapted for extensive lawns. Cedars were introduced into Britain as far back as 1683; and there are but few old country-seats that do not possess some specimens. Many majestic ones are met with in different parts; but in no situation have they thriven more prosperously than at the celebrated residence of Moor Park, in Hertfordshire. So numerous and large were they upon this estate—according to the *British Cyclopædia*—that about 1798 scores of them were felled for sale, containing four and five loads of timber in each of their stems alone. Cedars are trees of very striking character, and give an air of grandeur to every scene in which they appear.

Cedars may be raised from seeds which ripen in England, or from seeds imported from the Levant. When got from the cones, they are sown in seed-pans or boxes; and when fit for removal, the seedlings are nursed in pots, until they are large enough to be planted out in the open ground. While nurslings, many of them require a stake, to which a leader must be constantly kept trained, in order to insure a regular growth.

Deodar or *Sacred Cedar of India* (*Cedrus Deodara*). This is perhaps one of the most beautiful of the whole family of Coniferæ, its erect stem, and widely spreading, gracefully curved boughs, drooping at the tips, and clothed with the most beautiful green foliage. It grows on the mountains of Northern India, on heights of 10,000 or 12,000 feet. The Hindoos hold it in great veneration, calling it the Tree of God. Its wood is so durable, that specimens several hundred years old have been taken from Indian temples quite sound. Although the timber of this differs from that of the preceding species, still it is regarded by many botanists as in reality not specifically distinct. The deodar has been largely planted as an ornamental tree, during the last few years, being peculiarly suitable for pleasure-grounds, and especially for lawns and cemeteries.

Chili Pine (*Araucaria imbricata*). 'This noble tree,' says a recent writer, 'is, without exception, the greatest ornament among conifers;' and although still rare, is yearly becoming more common in pleasure-grounds. The male tree is said never to exceed 40 or 50 feet in height, while the female often attains 150 feet; but all the specimens in this country are as yet comparatively young. A deep light loamy soil is the most suitable for this tree. Its wood is yellowish-white, hard and durable, and well adapted for some ship-building purposes. It is regarded as quite hardy in Britain; but the early severity of the winter of 1856–7, browned the foliage of many specimens in different parts of the country, without, however, affecting their vitality.

The *Wellington Tree* (*Wellingtonia gigantea*). This is the great monarch of western forests, its gigantic proportions exceeding those of all other coniferous trees with which we are acquainted. According to Mr Lobb, it inhabits a solitary district on the elevated slopes of the Sierra Nevada, in latitude 38° north, longitude 120° 10′ west, at an elevation of 5000 feet above the sea-level; the trees there observed varied from 250 to 320 feet in height, and from 10 to 20 feet in diameter. One that was felled measured about 300 feet in length, with a diameter, including bark, of 29 feet 2 inches, at five feet from the ground; at eighteen feet from the ground, it was 14½ feet through; at one hundred feet from the ground, 14 feet; and at two hundred feet from the ground, 5 feet 5 inches. The trunk was perfectly solid. 'What a tree is this!' says Dr Lindley; 'of what portentous aspect, and almost fabulous antiquity! They say that the specimen felled at the junction of the Stanislau and San Antonio was above 3000 years old; that is to say, it must have been a little plant when Samson was slaying the Philistines, or Paris running away with Helen, or Æneas carrying off good *pater Anchises* upon his filial shoulders.'

This remarkable tree has been successfully introduced into this country by Messrs Veitch, through their collector Mr Lobb; and the young plants we have seen, appear to thrive well in our climate. To these gentlemen we are indebted for a specimen of the timber whence the microscopical drawing on page 579 has been taken, and we have also reproduced a portrait of the tree from their drawing. The timber is of a red colour, clean

and soft, resembling that of *Taxodium sempervirens* in general appearance.

The Wellington Tree (*Wellingtonia gigantea*).

The *Yew* (*Taxus baccata*) is more frequently grown as an ornamental than as a forest tree, and, like the cedar, it forms a plant suitable for places consecrated to solemn feeling. Its timber is very tough, and is adapted for making bows and staves, hence it is commonly ranked among hard-wooded trees. As an ornamental tree, it should be fenced round, or otherwise placed beyond the reach of cattle, as its foliage is highly poisonous; and being evergreen, is very apt to be browsed upon during the winter.

Yews are believed to be the most ancient planted trees of Great Britain; and no doubt can exist that there are individuals of the species in England as old as the introduction of Christianity, and there is every reason to believe very much older. It is the opinion of Decandolle, that of all European trees, the yew is that which attains the greatest age. The following are some of the more remarkable British specimens to which the attention of the curious has been directed. Those of the ancient Abbey of Fountains, near Ripon in Yorkshire, which yews were well known as early as 1155. Pennant says, that in 1770 they were 1214 lines in diameter, and consequently, according to Decandolle's method of computation, were more than twelve centuries old. Those of the churchyard of Crowhurst in Surrey, on Evelyn's authority, were 1287 lines in diameter. There are two remarkable yews still in the same cemetery, and if they be the same that Evelyn refers to, they must be fourteen centuries and a half old. The yew-tree at Fortingal in Perthshire, mentioned by Pennant, in 1770, had a diameter of 2588 lines, and consequently we must reckon it at from twenty-six to twenty-seven centuries old. The yew of Brabourn churchyard in Kent is said to have attained the age of 3000 years; that at Hedsor in Bucks, however, surpasses all others in magnitude and antiquity; measuring above twenty-seven feet in diameter; thus indicating the enormous age of 3240 years!

Hard-wooded Trees.

In this class are included a large number of trees with which every one is familiar. The list embraces—the oak, ash, elm, beech, chestnut, walnut, common sycamore, mountain-ash, whitebeam, acacia, birch, wild-cherry, laburnum, holly, hazel, box, and hawthorn. The following are the principal:

The *Oak* (*Quercus*) is the most valuable of all the timber-trees grown in Britain, not only because it is a hardy native, but for the many important purposes to which its durable timber, its astringent bark, and even its nutritious fruit, are applicable; and, moreover, for the delight which it gives to the eye in sylvan landscapes, the oak being the most picturesque tree of the forest when it has arrived at its mature age and form, and is still clad with foliage.

There are two species in our woods, natural or planted—namely, the *Q. Robur*, whose acorns grow singly and with long stalks; and the *Q. sessiliflora*, whose fruit grows in clusters, with short acorn stalks. The former is said to be the old Druidical British or naval oak, though the latter is more frequently met with, especially in woods which have been planted by the hand of man. Besides these two common sorts, which are natives, there are many other species, which are exotics—namely, the willow-leaved, the evergreen, ash-leaved; holly-leaved, of which there are six shrubby varieties; chestnut-leaved, scarlet, white, Italian, durmast, Luccombe, and the Turkey, of which there are four varieties, &c.

All the species are readily raised from their acorns. The young plants are transplanted twice or thrice in the nursery; and when four or five years from the acorn, may go to their final stations. Any kind of clayey loam is suitable for the oak; but a good gravelly loam, upon a subsoil of blue ferruginous clay, produces the finest timber in the shortest time. 'The largest oaks I have ever seen,' says Mr Brown, 'grew upon a dry sandy loam, with a free exposure to air; however, although the

The Oak.

oak may attain its greatest dimensions under such circumstances as these, we find it growing to the size of useful timber wherever it has the advantage of a soil with a dry bottom, and not too much exposed to storms—as, for instance, upon the top of a bare hill. The oak will not thrive or live long in a damp mossy soil.'

England, as well as Scotland, at one period possessed many noble and remarkable oak-trees, the remains of which are in some instances still to be seen, while in others they are only remembered in tradition.

The *Ash* (*Fraxinus excelsior*) is also a very valuable hard-wood tree, its timber being useful for many rural purposes, and particularly for implements and machines

The common ash, being prolific in ripening seed, is dispersed pretty generally over the face of the British isles. It should never be allowed a place in a hedgerow or on pasture-land, as its numerous surface-spreading roots absorb every particle of moisture, to the destruction of all other surface-plants. The circumstances favourable to the healthy development of the ash are, as regards soil, a good strong loam, rather rich than otherwise, and rather moist than dry—for the ash does not disagree with a little moisture, provided that this moisture have free and ready escape from the roots, and is not liable to remain in the least degree stagnant. The ash is also rather fond of shelter, and therefore, to grow it well, it is an advantage to plant it in a hollow or glen, or in the interior of a large plantation.

An ash-tree is in its prime, when by free and vigorous growth, it has attained a diameter of about twenty inches; for though on rich gravelly loam it will continue to increase until it is four or five feet in diameter, it has probably begun to rot at the core long before it has arrived at that vast bulk. Therefore, in order to raise ash-timber of the most valuable description, it is necessary to sow or plant a piece of land of the above character thickly, placing the trees about two feet apart. These will rise rapidly; and as soon as they appear to be choking each other, one half of the poles may be drawn, and the rest allowed to stand till they arrive at a marketable size, which is when they are from eight to twelve inches in diameter, and from forty to sixty feet high. When *ground-ash* is of these dimensions, it is suitable for every mechanical purpose where flexibility and extreme toughness are required. From its upright habit of growth, the ash forms one of our best forest-trees; and what is especially deserving of notice, its timber is better—that is, more tough, elastic, and durable—the more rapidly it is grown.

Seed should be gathered in the autumn, and immediately sown in nursery-beds; or the sowing may be deferred till spring. Some of the seeds may not rise till the second or third year; but as soon as the seedlings are five or six inches high, they should be rowed out to gain strength till finally transplanted. There are several varieties of the common ash, one of which is the weeping-branched, which, by grafting high on the tall stem of the common ash, forms a very ornamental weeping-tree.

The *Elm* (*Ulmus*) is a lofty tree, valuable both for its use in the arts and its ornamental appearance. The small-leaved or English elm is generally preferred for planting, particularly in hedgerows, avenues, and the like. This tree is not a forester, never being seen but about dwellings, or where dwelling-houses have formerly stood.

Besides the common wych-elm (*U. campestris*), found wild in the hedges of Britain, and which grows, where allowed, to a large size, yielding coarse-grained but useful timber, there are several other sorts. All delight in a gravelly loam, or in any soil which is not too wet; and they are well worth the planter's attention. No tree bears lopping or pruning better than the elm, it being hardly possible to hurt it by dismemberment. In the forest, it requires considerable space, as its natural habit is to throw out on every side broad spreading branches. When confined, it grows up with a slender weakly trunk, the timber of which is of little use to the carpenter.

The elm attains a very large size, and has a very rapid growth, both in Europe and America; but the elm of the latter country has a much more majestic appearance than that of Europe. Michaux characterises it as 'the most magnificent vegetable of the temperate zone.' A specimen mentioned by Decandolle, which grew near the town of Morges in Switzerland, measured 17 feet 7 inches in diameter, and was estimated at 335 years of age.

The *Beech* (*Fagus sylvatica*) is a native forest-tree, occurring most commonly on the chalky districts of the kingdom. When full grown, it is a beautiful and stately tree; and its timber is convertible into many kinds of domestic articles, very durable when polished by the cabinetmaker, and equally so if kept constantly under water.

Young plants are readily raised from the seed sown on beds, and covered with loose soil about an inch thick. Like other seedlings, they are, when five or six inches high, rowed out on fresh ground, till large enough to be transferred to their final stations. The beech is not at all fastidious as to soil; but a subsoil of chalk or limestone is most congenial. According to Mr Brown, few trees suffer less from mismanagement than the beech; and upon thin, poor soils, and even in high and exposed situations, no hard-wooded tree is so worthy of a place. He has seen the beech grow well upon a soil and situation where scarcely any other tree could have existed, not even the Scots fir. There are several species; the white-American, the dark-purple, and the dark-leaved, are ornamental, and are propagated by grafting on the common. As a forest-tree, none of the species are now extensively planted, in consequence of the comparatively little value set upon beech-timber.

At Newbattle Abbey, the seat of the Marquis of Lothian, a few miles south from Edinburgh, attention has been drawn to some remarkably fine large trees, most probably planted by the monks prior to the Reformation. Professor Walker measured a beech at this place in 1789; its trunk, where thickest, was seventeen feet in girth, and the span of the branches was eighty-nine feet. He thought that it must have been planted between 1540 and 1560. It was blown down a short time before the year 1809. It contained upwards of 1000 measurable feet of timber—twenty loads, or twenty-five tons—and was with reason reckoned among the largest beeches ever grown in Scotland. Another at Taymouth, of a like size, and seemingly coeval with this, was blown down when it had reached more than sixteen feet in girth. The large beech at Ormiston Hall, in Haddingtonshire, the bole of which we remember to have seen scooped out artificially into a shelter-house, was measured on the 10th of May 1762, and found to be eighteen feet ten inches in circumference. We believe it was quite entire when it was destroyed by a high wind. A large beech near Oxenford Castle, in Mid-Lothian, was measured on the 6th of June 1763. At the height of three feet from the ground, its circumference was nineteen feet six inches. This fine tree was then decaying.

The *Chestnut*, or sweet chestnut, sometimes also called the Spanish chestnut (*Castanea vesca*), is a splendid forest-tree, exceeding all other British plants in its huge mass of foliage; it is also valuable for its timber, which is but little inferior to the oak. In the south of Europe, it is chiefly regarded as a fruit-tree; but here, even in the south of England, in the finest summers, the fruit ripens but imperfectly. As a timber-tree, however, the Spanish chestnut deserves to be more generally planted than it has been of late years; and for a coppice or underwood plant it has no superior. For the number, the straightness, and durability of its poles, it excels all others, when a little trouble is taken to keep the growth perfectly regulated with respect to the purpose for which the crop is wanted. When timber or ornament is the object, the trees must constantly be divested of the shoots, which are apt to rise from the stem. A strong loamy gravel seems to suit this tree best; and young plants are easily raised from the nuts, dibbled in rows in the spring, and while in the nursery, kept free from bottom-shoots. The sweet chestnut requires considerable shelter, in order to permit of its full development; and should always be cut down before arriving at maturity, as the heart-wood is very liable to decay.

The *Common Walnut* (*Juglans regia*) is chiefly

regarded as a fruit-tree, but it is no less valuable for its excellent timber, which, from its lightness, durability, and beauty, and the high polish it takes on, is well adapted for house furniture, and is almost the only wood used for gun-stocks. Where its fruit is of no great value, and especially where it does not ripen, if planted among other forest-trees, it would be drawn up into a shapeable single stem, as valuable as many others. Young trees are readily raised from the nuts, like the chestnut, and are similarly managed.

The *Sycamore* or *Plane-tree* (*Acer pseudo-Platanus*) is a hardy native tree, which attains a large size, and grows more quickly than most of the other hard woods. It is employed for many common purposes, and in turnery. It not only grows to a large size, but lives to a great age. It prefers a dry sandy loam, with free exposure, but may be profitably planted in almost any situation, except in damp or mossy soil. The Oriental plane is one of those trees which attain the largest size, but the rate of its increase is not ascertained. In the valley of Bujùkdére, about three leagues from Constantinople, there is a plane which recalls to mind one which Pliny has celebrated. According to the Roman naturalist, there was a plane-tree in Lycia which had a hollow trunk capacious enough to accommodate the consul Licinius Mutianus and eighteen followers, who found within its ample cavity a retreat for the night. This living vegetable grotto was seventy-five feet in circumference, and the summit of the tree resembled a small forest. The plane at Constantinople is 150 feet round, and within it there is a cavity of 80 feet in circumference. This transcends the tree of Pliny. There are other very large Oriental planes mentioned by Clark and others; and one of vast size was lately noticed by Mr Quin in his voyage down the Danube.

The *Mountain Ash* (*Pyrus Aucuparia*), familiarly known in Scotland as the *rowan-tree*, from its beautiful clusters of red rowans or berries, is a tree of small dimensions, but elegant form, and is grown principally for ornament in shrubberies. It is hardy and of easy growth in dry soils, and makes an excellent skirter or outside tree in ornamental clumps and plantations; its finely formed foliage and white blossom yielding variety in summer, and its deep red berries as striking a variety in autumn and early winter. It should not be planted in town gardens or squares, as the berries attract the attention of mischievous boys.

The *False Acacia* (*Robinia pseud-Acacia*) is not only a highly ornamental, but also a valued timber-tree, when allowed to attain a proper size. Though a native of Virginia, and there called the *locust-tree*, it has been recommended as a coppice-plant for this country, on account of the very quick growth of its young shoots, which rise from roots after the stem is cut over; and for the excellent and durable quality of the poles for fencing, and particularly as props for hops and other trees. But whether planted thickly for underwood, or more openly for timber, the acacia requires much attention from the pruner during the first five or six years of its growth. It produces large luxuriant lateral shoots, which, if not stopped by having their points pinched off when they are about one foot long, are very likely to be blown off by the wind. This care may cease after the tree or pole is ten or twelve feet high, for after that height the growth becomes moderate. Young plants are raised from seeds or from layers, and thrive on any light sandy soil. The timber is highly prized by mill-wrights for cogs and other friction purposes.

The *Wild Cherry* or *Gean-tree* (*Cerasus Avium*) is a hardy native, but is seldom cultivated as a timber-tree; nor is that care bestowed upon it which it really deserves. The best specimens to be met with are those which have grown by accident in woods; but when such are felled, they are readily purchased by the cabinet-makers. The wood is very suitable for boring and for forming musical instruments. It is therefore a tree not to be neglected by the general planter, and should have a place among others. Young plants are raised from the stones, sown thickly on a bed of good soil, either in autumn or in spring, and afterwards rowed out to receive the ordinary nursery treatment, until fit to be finally planted.

The *Hornbeam* is an inferior forest-tree; its timber, however, is remarkably tough and durable, and consequently valuable to the plough and cart wright. It is a tortuous-growing tree, unless pruned when young.

The *Birch* (*Betula alba*) is another inferior timber-tree, but useful, as a coppice-plant, for many rural purposes. It has a beautiful and elegant contour, on which account it is introduced into ornamental scenery, especially if water be in the composition. Of the common birch there are several varieties, not to speak of the poplar-leaved, the tall, and the black American. Young plants are most conveniently raised from seeds, and the exotic species are raised from layers, &c. Wherever there are poor thin-soiled stony heights, the birch may be planted as a useful cover; its timber is readily bought up for gunpowder charcoal.

The *Holly* (*Ilex Aquifolium*) is a remarkably hardy evergreen, with smooth shining leaves furnished with prickly points. It is a native of Britain, and attains a great age, but seldom reaches a large size. Its timber is white and hard, which renders it suitable for veneering, and for making mathematical instruments. Different varieties are grown as ornamental shrubs. The holly hedges of Tyninghame, in East Lothian, have long been famed, being 11 feet broad, and from 18 to 25 feet high.

The *Box* (*Buxus sempervirens*) is generally grown as an evergreen shrub, but when planted out with a proper soil and climate, it attains a considerable height. *B. balearica* grows to perfection in Turkey, whence its timber is imported for use in all cases in which exceedingly fine cross grain is required. Sawn across and planed, its surface is as smooth and fine as polished metal. Box-blocks are on this account employed for wood-engraving.

Soft-wooded Trees.

In this section may be included the horse-chestnut, lime, alder, poplar, and willow.

The *Horse-chestnut* (*Æsculus Hippocastanum*) is only valued for the beauty of its flowers and the majesty of the full-grown tree in park-scenery. The timber is very inferior. There are several other exotic species—namely, the smooth, Ohio, ruddy, and the pale-flowered, all of which are easily raised from their large nuts. They require shelter and good rich soil; they grow rapidly under these conditions, and soon form highly ornamental objects. A section of this genus is called *Pavia*, or bucks-eye, the fruit being round and smooth. The flowers of some of these last are magnificent, being of a glowing red, and are most conspicuous in the spring or beginning of summer. Avenues of these trees, as seen in the neighbourhood of Geneva, present a gorgeous appearance when in flower. The pavias are often propagated by being grafted upon the common horse-chestnut.

The *Lime* (*Tilia*) is a beautiful leafy tree, grown chiefly for ornament, and very suitable for avenues. As all the varieties require a heavy soil and sheltered situation, and their timber is not of corresponding value, they are seldom or never introduced into the forest. The lime is the European tree which, in a given time, appears capable of acquiring the largest diameter.

The *Alder* (*Alnus glutinosa*) requires a damp bog-earth soil, and is only planted by streams, or to occupy a spot where nothing better will grow. It is most profitably kept as underwood, large poles suitable for the turner or for piles or planking for bridges, fetching a good price.

The *Poplar*.—There are several species—as the common black poplar (*Populus nigra*), the trembling poplar,

the Lombardy poplar, &c. They grow rapidly, and the last mentioned rises to a great height, but narrow in mass, so as to be very conspicuous in hedgerows and landscapes. The timber is soft, but a good deal sought after; and where undrainable spots are wished to be decorated with stately trees, no better kind can be chosen.

The *Willow* (*Salix*) is an extensive genus, comprehending those shrubby species, the osiers, used for basket-work, as well as a few species which attain to the height and character of trees, the best of which, as yielding very good timber, is the white or Huntingdon (*S. alba*). Another of the tree-willows is that elegant plant the Babylonian or weeping willow, which forms so suitable an accompaniment to pieces of water, whether artificial or natural. The common osier is the sort mostly cultivated for the basket-maker, and the annual crop of rods from established stools pay the owner as well as any other crop on the farm. All the kinds are easily propagated by cuttings, and require to be grown in wet soil.

REARING OF TREES.

Trees grow spontaneously in all countries in which soil and climate will permit, and, as is well known, form forests of many hundreds of miles in extent on the North American continent. Whatever be the peculiar nature of any species of tree, it appears that the dimensions and form of all are more or less affected by their relative situation. If crowded, they have a tendency to grow tall and slender; if left abundance of space, they extend in breadth. The comparative absence or presence of air and light causes this. In a forest, each tree struggles upwards; whereas the tree in open ground shoots out lateral branches nearly from the bottom of the trunk, and attains a mass of foliage.

All exposed trees have the largest roots; being liable to be blown over, they take a much firmer hold of the ground than if they were sheltered on all sides; in other words, the action of the tree, and the free air and light, induce the development of numerous branches and a large breathing apparatus of leaves, and the tree must have a corresponding mass of roots for the supply of sap. So exact is this correspondence between the exposed and underground portions of the tree, that the extent of roots may sometimes be judged by the extent of branches. The practical lesson acquired from these facts is, that if trees are to have large bushy heads, they must be planted widely; and if wanted to be tall and slender, they should be crowded.

Ornamental Plantations.

Even on the smallest possessions, a sprinkling of forest-trees in the hedges or corners of the enclosures gives a dignity to the spot which otherwise it would not possess. There cannot be a more cheerless object in a landscape than a house—however substantially built—standing naked and alone, without a sheltering tree or bush to indicate either the taste or competence of the occupiers within. The lowliest hut, environed by two or three aged oaks or hawthorns, is an interesting spectacle, and far more delightful to the eye than the proudest palace standing bare and unaccompanied by trees.

In ornamental planting, there is much room for the display of good taste. It is now allowed by all who have studied landscape-gardening, that in the part surrounding the mansion, trees should not be dotted about at equal distances, nor in lines, neither should they be placed as blinds to the principal windows, but so arranged as to form irregular glades, diverging in as many directions from the house as is consistent with effect and propriety. These glades should always be laid out with reference to some distant interesting object, or some striking feature of the surrounding country. The offices, which are generally in the rear, or at one end of the house, should be hidden by a screen of trees and shrubs; and all eyesores, visible from the windows or elsewhere, should also be screened by plantation.

When it is intended to increase both the beauty and the value of an estate by planting, either for the personal interest of the proprietor, or with a view to that of posterity, ordinary prudence will direct him to fix on those parts which are the least valuable for agricultural purposes. The precipitous slopes of an undulating surface, where cultivation is difficult or impracticable, moist swampy hollows, or the ridges of bleak hills lying to the northward or eastward, will all be found eligible for conversion into woodland. And while such plantations yield the finest shelter and cover for game, they rapidly add to the real value of the estate.

It has already been observed that some proprietors may think it advisable to plant only the inferior portions of their property; while others, who wish to have a tastefully planted park or a highly embellished estate, place their groves, or groups, or single trees, on any eligible spot, without regard to the quality of the soil. In this case, everything is sacrificed to obtain such a disposition of the trees as will produce the most striking scenic effect; and such kinds only are selected as blend harmoniously with each other.

The character of the general surface surrounding a mansion fixes the style of planting and the kinds of trees. If the surface be moderately undulating, having easy swelling knolls and gently falling hollows, without asperities of any kind, such a surface is said to be beautiful, and consequently the plantations should be beautiful also; that is, composed of trees of the finest foliage and most elegant forms. But if, on the contrary, the surrounding country be wild in character, and marked with bold and rugged features, as naked rocks or cliffs, deep ravines or glens, &c., then a different style of decoration must be pursued —as planting in irregular masses all the most grotesque, rugged, and sombre-tinted trees that can be selected, in order to harmonise with the natural features of the country. Scenery of this kind is said to be picturesque; and where such tracts of country are chosen for a manorial residence, and the grounds are laid out and planted by a skilful gardener, the scenery is much more interesting to the eye of taste than any other, especially if water chance to be in the composition. The grounds of Dawick, in Peeblesshire, afford a fine example of ornamental plantations, which have been increasing in beauty for many years, under the taste and management of their proprietor, Sir John Naysmith, Bart.

Great changes occurred in the style of planting during the eighteenth century. Up to the beginning of the reign of George I., all transplanted trees were arranged in right lines, as single, double, or quadruple avenues or vistas, or as boundaries to the enclosed grounds belonging to royal or other palaces, colleges, and public buildings. But about this time it was discovered that trees in rows were rarely seen in the works of the great masters in the schools of painting: a new idea was entertained that such a disposition of trees was inadmissible, as being too stiff, formal, and not agreeable to nature; a sentence of condemnation was accordingly passed upon private avenues, and they quickly disappeared before the axe of the woodman. A few only were saved, and now comparatively few avenues are planted. Along with the avenues, the old regularly laid out terraces and flower-gardens were swept away to make room for a new style, distinguished by the prevalence of *irregularity* and *curved outlines*.

Soon after this revolution in landscape-gardening, a great many ridiculous pranks were played in

obtaining *extreme* irregularity and *tortuous* lines; and some of the performers got severely handled by the satirists of the day. Kent, who began the revolution, died without having gained much reputation; but his successor, the famous 'Capability' Brown, became highly eminent, and was universally employed. He did more in altering the gardens and grounds of the country-seats of these kingdoms than any landscape-gardener before or since his time. His aim was to produce unmixed beauty by neatness and general smoothness, especially near the house; for which purpose he cleared away every obstruction, whether built or planted, in order to set the mansion fairly out upon a naked grass-plot or lawn. Even the kitchen-gardens were removed as far off as possible; and every bush, or other appearance of inequality, was shaven off, to produce the wished-for smoothness. In this proceeding he and his copyists fell into the opposite extreme; instead of beauty, *baldness* was the result; instead of intricacy, *tameness;* and instead of the embosoming shelter of surrounding groves, complete nakedness, and exposure to every wind that blows. Nevertheless, Brown had the honour of laying out many beautiful parks and gardens, which remain to this day as monuments of his good taste and judgment; but many of his immediate followers brought discredit upon his style by their very awkward and unmeaning imitations.

The severe animadversions published against the Brownian style tended to correct some of its author's most ostensible errors; and the works of Repton, Loudon, and others, have improved the style of English landscape-gardening, and brought it much nearer to the principles of real taste. The *clump* and the *belt* have been greatly modified; the first is now expanded into a less formal group, and while the latter has lost its continuity, it has been increased in depth, and its lengthened form as a boundary judiciously broken. Undergrowths, which were swept away by Brown, are again introduced; and the banks of lakes and rivers, formerly smoothed down to the water-level, are now left more abrupt, broken, and irregularly fringed with overhanging trees, and aquatic shrubs and herbs.

Forest-planting.

The different methods pursued in establishing or laying down woodland, depend in some measure upon the number of acres and the nature of the ground. Nevertheless, there are certain points which in every case are worthy of the planter's attention; such as the best form for any given extent, the style of boundary, and the mode of enclosure. On these heads we transcribe the advice of a practical forester of long experience. 'As the future welfare of a plantation is considerably affected by the manner in which it is laid out, no man ought to attempt the laying out of ground, who is not naturally possessed of good taste for that sort of landscape scenery, which is based upon the laws of nature, and which will enable him to lay out the proposed plantation in such a manner as to give the greatest possible effect in ornamenting the neighbouring country. It is also necessary that the person who would lay out ground for a new plantation, should be possessed of a knowledge of the nature of the growth of each sort of tree when planted upon any given soil or situation; which knowledge will enable him to judge rightly as to the effects that certain trees will have when planted in any given spot; and he will also be enabled from such knowledge to say truly whether or not trees will grow well in the situation chosen for a new plantation. It is further necessary, in the laying out of a new plantation, that he should be acquainted with, or at least have in view, any local peculiarities of the district relative to cold and destructive winds from certain points. From such knowledge he will be able to lay out the proposed plantation in such a manner that it shall have the greatest possible effect in giving shelter to the surrounding fields, which is the principal end a proprietor aims at in having woods upon his estate.

'The larger that any piece of plantation is, the sooner will the trees come to useful size, and answer the desired end; the smaller it is, the more likely are the hopes of the planter to be disappointed. And the reason of this is obvious: for the young trees growing in an extensive plantation, as soon as they rise a little above the surface of the grass or heath, begin to shelter one another; whereas if the plantation be narrow, the young trees can hardly be said ever to come the length of sheltering one another—for every breeze of wind blowing through the whole breadth, acts upon every single tree almost as powerfully as if each tree stood singly and alone. Therefore, it is most profitable for proprietors always to plant in large masses. Trees planted in a mass of one hundred acres' extent will be more healthy, and come sooner to profitable size, both as affording timber and shelter, than they would if planted in a mass of ten acres. From this it follows, that if a proprietor wishes to plant one hundred acres upon his estate, he will raise more healthy timber by planting in one mass, than he would do by planting the same extent in four masses of twenty-five acres each. No young plantation, upon an exposed situation, should be less than one hundred yards broad at any given point; and where the soil is of a light, thin, mossy nature, and not apt to raise trees to good size, one hundred yards may even be too little for breadth.'

Again: 'The method of laying out plantations in the form of strips, so often to be met with in Scotland, gives a poor and mean appearance to a gentleman's estate, particularly when found about the home grounds. The form in which they have generally been made is in straight lines, from twenty to thirty yards broad. In such narrow belts of wood, the trees are very seldom found in good health; and, upon a little consideration of the matter, this is not to be wondered at—because, from the narrowness of such strips, the proprietors were always afraid to thin them, wishing to keep them in a thick state, in order to give as much shelter as possible; and the natural consequence is, from being left too thick, the one tree soon kills the other. And even where such strips have been well managed, it cannot be expected that they could produce either good healthy timber or make a good shelter; for, being so narrow, the trees never come to shelter one another. But it is a happy circumstance in the history of arboriculture, that few such strips are now planted: gentlemen are now beginning to see the impropriety of such a method of raising plantations; and now, in almost all cases of good management, we see the old-fashioned narrow strip giving place to the well-defined, extensive plantation, which is, indeed, the only profitable way of rearing trees for any economical purpose.'

Further: 'It is absolutely necessary that every piece of ground laid out for a plantation should be fenced in some way or other, previous to its being planted. A fence not only prevents the inroads of sheep and cattle, but it at the same time tends very much to shelter the young trees, and to bring them on rapidly. It is, indeed, surprising to observe the difference that a very low fence makes upon the growth of young trees, as compared with those which are not protected by one. Any proprietor or forester, upon looking through his several plantations, will observe that, in all young plantations, the most rapid-growing, and at the same time the most healthy trees in it, are to be found immediately behind the outer fence; and, upon the other hand, in all older plantations, the best grown, and at the same time the most healthy trees, are to be found in the centre of the same, or at least a considerable distance back from the fence. Now, it may be asked, what is the reason that the best wood is found in

the inner parts of old plantations, while the most rapid-growing trees are to be found, when young, behind the boundary-fence? The reason, as proved from experience, is this: During the first eight or ten years of the age of any young plantation, the boundary-fence is the only shelter that the young trees have; and it is evident that those trees which grow immediately behind the fence will receive most of the benefit of its shelter; consequently, from the circumstance of their receiving more shelter than their neighbours further off, they grow more rapidly, until such time as their tops begin to rise above the level of the fence, when they are considerably checked by the cold winds. At this stage they begin to grow thick and bushy, rather than advance in height; and immediately upon their becoming so, they begin to shelter all their neighbours inside, which, again, begin to have double the advantage of their neighbours outside; for the trees upon the outside had shelter only so long as they were below the level of the top of the fence, whereas those inside have now a shelter which every year increases upon them for their advantage, in height as well as in thickness. All this goes to prove that a fence is a great means of furthering the healthy development of a young plantation, independent of its protecting from the inroads of cattle at the same time. I always calculate that a plantation with a good fence is ten years in advance of one without such protection.'—*Brown's Forester.*

We must now notice the more approved practice applicable to the better kind of soils. In one of the prize-essays of the Scottish Arboricultural Society, published in the Transactions (1857), Mr Thomson, of the Royal Forest, Chopwell, offers the following valuable observations on this head: 'Planting is a work of the greatest importance, and cannot be satisfactorily executed unless there is due preparation made for it. We often see large tracts of land surcharged with water, and growing only the veriest rubbish, having a few forest-trees studded at irregular intervals over the extent; but such is not planting in the true sense of the word. We apprehend the first thing necessary to attend to in this respect is, to have the grounds carefully laid out into the required form, which, as a matter of course, will have to be regulated by the natural undulations and general outline of the grounds upon which the plantation is to be formed, and the position and aspect which it is desired it should assume. It will, however, be found advisable, in all cases where practicable, to have one side made as much as possible in a convex (or cuneate) form, with the tip of the cone pointing in the direction whence the prevailing winds of the district blow; this is in order that the force of severe gales may be broken, and not allowed to burst with their full force upon the whole body of the plantation at once. This is a consideration of paramount importance everywhere, but more especially in high-lying and exposed districts. The next step is to have the land properly fenced, in whatever manner may be found cheapest and most efficient; whether by stone-dikes, thorn-hedges, or wire-railing, must depend upon local circumstances and individual judgment and taste. Following immediately upon this, drainage of the land, in all cases where found necessary, should be carried out. Having these preliminary particulars fully completed, and having determined upon what kinds of plants are required, the next step—and a vitally important one it is—is to make a careful selection of the plants that are to be employed. This is a duty no forester who consults his employer's interest, or who has respect for his own character and professional standing, will neglect, seeing that if diseased or otherwise inferior plants are obtained, the whole operation will inevitably end in failure and disappointment, and the expense both of plants and planting will have to be again incurred; and not only so, but the diseases which most commonly infest nursery stock are of a very contagious nature, and will, to a certainty, contaminate the whole adjoining neighbourhood; and when they once obtain a hold in any district of country, it is by no means an easy task to effect an eradication. The greatest judgment and care must therefore be exercised in the selection of forest-trees; it must be seen that both roots and stems are free from bug or other disease, and that they are of a size suitable for the soil, situation, and climate wherein they are to be planted.'

With respect to the choice of trees for different soils and circumstances, Mr Thomson observes:

'With a view to profit only, larch should be more extensively planted than any other kind of tree, as it grows very rapidly, is in constant demand, and generally sells at a remunerative price. Approximate calculations shew that two crops of larch can be brought to maturity in the same space of time required to bring one of oak to perfection; and supposing that both are equally well situated as regards external circumstances, the several sums realised for the former, with accumulated interest, will more than double the amount of income derived from the latter. The timber of the larch is suitable for a great variety of purposes, and, with the single exception of the ash, can be more generally appropriated to mining and country uses than that of any other kind of tree our land produces. When it is grown upon good sound land, and found close and firm in the texture, it is in many cases preferred to the best Memel; and I could name many instances where it has been selected while the other was rejected. The larch will grow healthily on almost any kind of soil free from extreme dampness, but it is not advisable to plant it on very light or sandy land; on which it soon exhausts all the amount of nourishment the soil affords, and prematurely decays. . . .

'The oak, also, is a tree which will be planted as long as planting continues. Deep loamy soil, or a mixture of clay and loam, upon a rocky formation, is the best adapted for its rapid growth; but from the far-spreading and searching nature of its roots, it will thrive on what is termed "bare rocky ground," if there is sufficient depth of soil wherein its roots may become firmly established; and when once established, it is well known the amount of endurance it will undergo rather than relinquish its hold. On light or gravelly soils, the oak ought not to be planted, as it very soon becomes stunted in its growth upon all such, and never succeeds to large or profitable dimensions. The oak is also valuable on account of the bark it produces, which is employed in tanning. The ash and elm are somewhat similar to the oak in their natural characteristics, and can be successfully grown under much the same general circumstances; only, to grow healthily, the land upon which they are planted should be considerably drier than such as the oak will succeed well in, though it also delights in a dry soil. If dampness pervades the soil upon which these trees are planted, both kinds, but more especially the ash, will soon become covered over with moss and lichen, from the injurious tendency and effect of which it is next to impossible to relieve them. Neither should they be planted upon gravelly soils, as I have observed that in all such cases they invariably decay at an early stage of their growth; and though they may continue to *exist* for a moderate length of time, they do not proportionally increase in bulk and stature, and must therefore, as a natural sequence, become deteriorated in quality. Where all these kinds of hard-wooded trees—the oak, the ash, and the elm—succeed best, is on a loamy or alluvial soil, with a subsoil of clay, situated upon a substratum of rock or gravel. In marshy places, or along the margin of lakes, water-courses, &c., the birch, the alder, and the poplar may be planted to any extent, as they luxuriate in low-lying grounds, which being their natural habitat, is of course most congenial to their growth. The birch will also grow well on moderately dry lands.

'All these trees are undoubtedly natives of Great Britain, and in the northern parts of the island are frequently to be met with, of themselves forming extensive and valuable plantations. They frequently grow to large dimensions, and possess the additional advantage that they will succeed where scarcely any other forest-tree would thrive, and but for which, vast tracts of land would be allowed to remain perfectly waste; whereas, with their use, the very poorest may be turned to profitable account. For planting on light or gravelly soils, the Scots pine should be principally selected, seeing that it flourishes upon the poorest lands, and in the most exposed situations. The *Pinus Austriaca* has to a certain extent superseded the planting of Scots firs during the last few years, and is *supposed* to constitute a good substitute; but its general applicability to the soil and temperature of Great Britain not having yet been fully tested, and possessing, as we do, but little information of its quality as a timber-tree, it would appear to be unadvisable that it should be introduced to the entire exclusion of our own native pine. The timber of the Scots fir is useful for many purposes, and, when fully matured on land favourable to its growth, far surpasses in quality much of the timber imported from foreign countries; whilst no other tree whatever equals in amount the shelter it affords. Even in the most mountainous and exposed districts, and on the barest lands, it thrives in an extraordinary manner; and considering that it combines, in an eminent degree, extreme hardness with general practical utility as a timber-tree, and seeing that it possesses such powers of contending successfully against difficulties in the form of soil, temperature, and aspect, we would earnestly advise that, instead of allowing it to become obsolete, more and more attention should be bestowed on the culture of the real native sorts, and that it should be more extensively planted than ever. The spruce fir also thrives well on light soils; and where the temperature is mild and humid, it forms an excellent tree for admixture with others of various sorts. It will not, however, endure the same amount of exposure as the Scots pine, and should not, therefore, be planted at any considerable altitude; but in moderately elevated situations, it may, with propriety of taste and judgment, be largely introduced, as the shelter it affords is of the greatest consequence to plants of a more delicate nature, and it likewise possesses such natural beauties as to warrant its being cultivated in all woodland scenery. The beech and sycamore, if not altogether so hardy, without doubt, stand next in that respect to the Scots pine, and will grow most luxuriantly on even the poorest of soils.

'With reference to the beech, I have seen it attain to large dimensions on pure sand; but the soil best adapted for bringing this tree to the greatest perfection, is a marly or gravelly clay on a chalk formation, on which it attains to the most elegant stature and beauty. In the south of England—in some cases exposed to the severity of the south-west gales—it grows in a comparatively short space to the most admirable dimensions; and though its timber, on account of its brittleness, is inferior to that of most other hard-wooded trees, the natural and picturesque gracefulness of a good specimen of the beech is such as to command for it a prominent position in every gentleman's park; and, with a view to ornament, we would be fully disposed to class it amongst the first of our indigenous trees. The sycamore also delights in a light soil, and being of a very hardy nature, will thrive well, and may be profitably grown on exposed situations, either by the sea-shore or on high-lying districts. Its timber is of considerable value when of large size, and is applied to many useful purposes. Upon the whole, the sycamore and the beech are much akin in their natural habits, and may be grown under circumstances almost identically the same.'

The same authority observes: 'In no case does it appear to me advisable that hard-wooded trees should be planted alone or in excessive numbers; for even if a hard-wood plantation be desired, it is better, in the first instance, to plant the requisite sorts amongst a variety of the fir tribe, so that they may be duly sheltered and protected in their youth. Both kinds should also be planted at the same time. We have seen many examples where the nurses have been planted a few years before the hard-wooded trees were put in, preparatory to which last, certain quantities of the firs had to be removed; but the practice is antiquated, and indisputably a bad one, simply because it produces the very effect which it is intended to avoid. Ostensibly, this is the production of an abundance of shelter, or that the hard-wooded trees may grow more exuberantly than they otherwise would do; but it ought to be recollected that the firs grow much more rapidly than any hard-wooded tree which is cultivated for the sake of its timber, and doing so, completely shade and overtop the more valuable sorts, to the entire exclusion of both light and air, without which it is absolutely impossible that any plant in the whole vegetable kingdom can prosperously succeed. The system I myself practise is—first, to determine at what distances apart the hard-wood trees ought to be placed—say from nine to twelve feet—and having these carefully put in, I next proceed to have the spaces between these plants filled up to suitable distances with firs which have been selected for the purpose. On low-lying grounds, the distances between the plants, over all, need not be less than from three and a half to four feet, beyond which it is unnecessary to extend them, as the thinnings, at even this rate, will be of some small value when the operation of thinning is first required; but on more exposed and colder situations, the rate of planting may be reduced so low as even two and a half feet from plant to plant. The best nurses are larches, Scots pine, and spruce firs; and they may very advantageously be planted in the ratio of two of the former to one of either of the latter, as such a course will be found to be equally beneficial with any other, and decidedly the most profitable.

'As to the time or season of the year when planting operations may be most satisfactorily executed, I would unhesitatingly record the matured opinion I have derived from extensive observation and practical experience, that all such should be conducted and concluded in the four months of November, December, January, and February. . . . On damp lands, and where late spring-frosts prevail, planting may be postponed till the very latest of the dates I have noticed; but if prosecuted beyond this, the operation cannot reasonably be expected to succeed. If the plants are to be put in by the system of what is technically called *pitting*, the pits may be prepared any time before; and the longer previously they are so prepared, so much the better, as the soil cast out of the pits, being exposed to frosts and the ordinary action of the weather, becomes thoroughly pulverised and purified; and is thus put into a sound and healthy state for the reception of the roots of the young trees.

'With regard to the *method* of planting, I consider it preferable in all cases to prepare pits for hard-wooded trees of all kinds, as they require a considerable space to develop the large fibrous roots with which they are, or ought to be, furnished. The dimensions of these pits must be regulated by the size of the plants they are designed to contain. In ordinary cases, I would say that pits from twelve to fifteen inches in diameter would suffice for every necessary purpose; they should also be made perfectly circular, and fully as wide at the bottom as the top. Pitting will also be requisite for all kinds of firs, where planted on stony or any kind of hard ground; but in loamy, or any other sort of friable soil, I find the ordinary system of notching to be

decidedly the best, and by far the cheapest. Where, however, pitting is found to be indispensable, I would advise that the expense of casting the soil actually out of what may be termed the pit, and replacing it again, should not be incurred; as, if it is well stirred all round to the required dimensions with the end of the mattock—the utensil employed in this service—the whole advantage resulting from the system of pitting is equally well secured, the plants are more easily put in, and the cost is comparatively trifling. Trenching may also be found necessary in some isolated cases, but the enormous expense it incurs precludes its general application, even though it were advantageous in every instance, which is not the case. However planted, the utmost care must be exercised, so that none of the roots of any fir may be cut off with the edge of the spade, which is too often done by ignorant or careless labourers; and though not easily detected when committed, this species of injury is doubtless the parent of many of the casualties which occur in the earlier years of some of our plantations. Due regard must also be had to the *sizes* of plants most suitable for different localities, with respect to situation and climate; for moderately sheltered grounds, I would say that oaks about one and a half foot high, one and two years' transplanted larch, two years' transplanted Scots fir and spruce, would be found to be the most suitable; on more exposed situations, two years' seedling larch, with one year transplanted spruce and Scots fir, will answer better than those of a larger size.'

When a large extent of *inferior* land is intended to be planted, it must necessarily be executed in the most economical manner, and without many of the preparations above recommended. If the surface be irregular, and covered with short herbage, two or three year old plants of larch, Scots fir, birch, intermixed with a few oak, beech, and ash, may be inserted at proper intervals by forming notches in the turf. One or two blows of the tool raises a triangular piece of the surface, under which the root of the plant is properly placed, and the raised sod turned back and trodden down with the foot. In this simple and expeditious way of planting, many hundred acres of hilly land have been stocked with trees; and though many of the plants are liable to suffer, if a dry summer follows the planting, a majority are sure to succeed, which well repays the cost. Notwithstanding the risk of being defeated in such attempts, it is quite certain that in numberless cases they have succeeded admirably; and very valuable woods now ornamenting both England and Scotland have been raised under these simple modes of planting. When such ground is level, an opening is made by first cutting the turf in the shape of a cross, and turning back the four corners from the centre, breaking up and making a hollow for the root; when the tree is placed upright, the turf is returned and trodden firmly down.

But in planting rough unprepared ground, especially where it is very hard, it will sometimes be found advisable to incur the expense of *pitting*, even where the pits have not been prepared beforehand, as above recommended. The surface-covering is first cleared off, the pit broken up with a mattock, and the loose earth thrown out with a spade; the tree is then placed, and planted with the removed soil.

Before planting, it is always necessary, as we have stated, to see that the land is properly drained, otherwise good timber cannot be produced, and it may be advisable to notice briefly some of the points to be kept in view in draining. The number and extent of the drains will be regulated by the extent of plantation and wetness of soil, which will also indicate the proper distances apart. A depth of between one and a half to three feet is recommended by Mr Rutherford, who, in the *Transactions of the Scottish Arboricultural Society*, makes the following judicious observations on this subject:

'Before commencing active operations in any portion of land about to be drained for planting, great care must be taken in the selection and provision of a proper outfall. This is of such vital importance, that, were it not attended to, the whole drainage might be rendered totally inefficient, or, in fact, it could not be executed at all. On level land this is more particularly the case, and its perfect execution, both in laying out and cutting, resolves itself into an absolute necessity. Where a large tract of level land has to be drained—a circumstance not likely often to occur—this superfluous absorption causes an increased evaporation from the stem and leaves, the consequence of which is, that a lower natural heat prevails in the plant, and the chemical changes on which its growth depends proceed with less rapidity. The air ought to be able to penetrate into the soil, being, as it is, so essential to the preservation of a proper temperature and to the ramification of roots; and this it can never do in soils where there is an excess of water. To remove, then, this free water, which is the source of so many evils, the cause of so much disease, and the destroyer, consequently, of many sanguine expectations, ought to be the first care of every arboriculturist. Unless this be attended to, no successful result can be attained; the progress of plantations will be tardy; the individual members of them will become deformities, when they would have been ornaments; they will become sickly and die, when they would have been healthy, and yet growing vigorously. . . . The principal object in view in draining wet land is, to cause the whole of the rain-water falling upon the surface of the ground to penetrate readily to a desired depth, and to discharge this water at once, not allowing it to accumulate in the subsoil. This done, the soil becomes pervious, and is then in a fit state for the operation of the planter.'

When ornamental plantations are made in a park, and especially if they are in view from the principal windows, it is desirable that they should rise as quickly as possible, for the sake of immediate effect; the trees, therefore, receive careful treatment. The ground is not only deeply trenched, but a most liberal dressing of good rotten dung and vegetable mould—the first trenched down, and the latter dug into the surface—is bestowed, which of course excites the trees into much stronger and more rapid growth than if only the ordinary expedients were employed. But this superior and expensive practice is seldom necessary, and much seldomer executed. Indeed, in the rearing of extensive forests for valuable timber, it would be decidedly injurious; for though the young trees might rise rapidly for a few years, as soon as the exciting influence of the manure was over, they would, as all experience teaches, soon fall into a diseased condition, and never attain that hardy robustness which natural forest-timber always presents.

Pruning—Thinning.

When woods are planted as a source of profit, a material part of their subsequent management consists in the labour of pruning and thinning the trees. It is not enough that trees shall grow and be annually increasing in bulk; they should also be assisted to take the finest and most valuable forms, and this in fact greatly affects their increase. A round straight bole, of moderate length, is more useful and saleable than a crooked knotty one of twice the size. To have fine timber, it is absolutely necessary to bestow a little trouble to start them fairly off, during the first ten or fifteen years of their growth.

To have tall and straight stems, the trees are planted thickly at first, about four feet apart, or even less; and if in the spring the woodman pays his annual visit, armed with a light keen bill, he may direct the growth with the best effect. Every lateral branch that appears to be attracting too much of the powers of the plant, and especially if, as already observed, it be contending

for supremacy with the leader, should be cut off *close* to the bole as soon as it has attained the diameter of an inch. Such a wound will be soon healed up, and present no flaw when the tree is cut up at the saw-pit. If branches are allowed to remain until they have acquired a diameter of from two to four or more inches, and then cut off either close, or, what is much worse, at some distance from the bole, the timber is deteriorated. Such wounds will be healed over in time, but the timber will be wanting in its best property—namely, soundness and freeness from knots.

Trees grown for ornament in lawns require no other pruning than what may be necessary for the removal of rotten or decaying branches; and in general it will be found advisable to leave each kind of tree to assume its own natural form. Ornamental trees are always most beautiful in their proportions when the branches and spray tend towards the ground; but this will not be the case if cattle are allowed to browse beneath and around them. These animals nibble away all the foliage and spray within reach, so as to form an even bottom of foliage, anything but agreeable to the eye. The only plan of avoiding this inelegance is to exclude browsing animals altogether from ornamental grounds; but this is attended with opposite evils, and takes away that pleasing assemblage of forms which is the great charm of woodland scenery. Where cattle or sheep are permitted to browse, all young trees at least must be protected by circular palings, otherwise they would be barked, and generally destroyed.

All species of the hardy pine and fir tribe intended for profit should be planted pretty thickly, and thinned when young, leaving a full number of permanent trees to grow up to a marketable bulk. The fine clear-grained timber imported from America and the north of Europe is the produce of trees which were never pruned; growing up in very close order, the lower spray is consecutively killed by the want of air and light, shut out by the close canopy of branches above. This is gaining sound timber by accident, which may be done in any country, but by no means in such a short time as by hand-pruning.

Mr Philip, of Aldbar, states that trees increase in thickness fastest when they have about two-thirds of their whole height covered with branches during the whole period that they are increasing in height; these ought to be diminished to between one-half and one-third of the height for a top, according to the sheltered or exposed situation they may be in, care being taken not to draw them up too fast, and then allow them to get top-heavy, as this would bring on too much strain both on root and stem, which in soft soils is very injurious to the tree. 'Every tree,' he observes, 'has its own habit; and the pruner must, in a great measure, adapt himself to the habit of the tree he has to deal with, and not force them into any shape which may please the fancy of the operator. We can only assist nature in her operations. One tree such as the poplar, has a natural tendency to keep to one leading shoot, and to keep its branches within a comparatively narrow space; while the oak has the opposite tendency, if left to nature: its habit is to have a short stem with a wide-spreading top, which may be a beautiful object in certain situations, but certainly not profitable as a timber-tree. Pruning is so closely connected with, and dependent on judicious thinning, that attention to it is of great consequence; for to thin the trees to wide distances will cause them to throw out strong side-branches, and this creates additional work to the pruner; but by keeping the trees pretty thick on the ground, the branches are confined within reasonable limits, and consequently kept from increasing to a large size. The method which I adopt is, by thinning and pruning, to keep the trees standing quite clear of each other, to allow free circulation of air, and admit the light all round them—both of which are essential agents in the growth of trees; and by this means I manage to keep the trees in a healthy growing state, and prevent the branches from becoming large, which always detracts from the value of timber, except where bends and *knees* are formed fit for ship-building. The tools which I use in the operation of pruning are—a strong pocket-knife, hand-saw, a saw with the teeth reversed, and the pruning-shears; the last two are fixed on long poles, and they save much loss of time in climbing: for trees further advanced, a ladder fourteen to eighteen feet will be found necessary.'

Transplanting.

Trees may be lifted from one place to another, or transplanted. The art of accomplishing this exceedingly delicate operation was chiefly developed by the late Sir Henry Steuart of Allanton. The transplanting of a full-grown tree has in all ages been deemed next to impossible; and when it was attempted, the operator thought it necessary to cut off a great number of the branches—and consequently the leaves—from an idea that, if suffered to remain, they would require more sap than the roots could supply in their new situation; but this practice was found to be injurious.

Sir Henry Steuart practised the art of transplanting on what he called the preservative principle—without mutilating either roots or branches. His seat, Allanton House, was situated on an irregular slope, on the right bank of the river Calder, a tributary of the Clyde. The neighbouring ground, though diversified, had no very picturesque natural points; but he contrived, by the removal of large trees, and forming an artificial lake and river, to realise in some measure the miracle of bringing new and picturesque scenery into actual existence, in a short period of time.

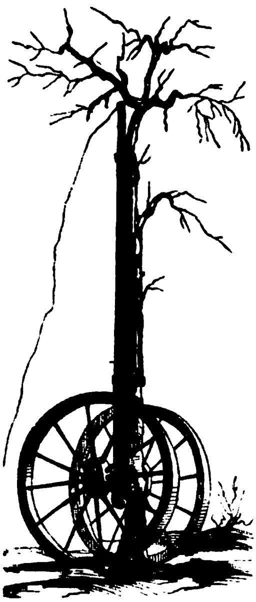
When single trees are to be planted on a lawn, a space of from four to six feet is stripped of the turf, which is rolled back; the soil within should be deeply broken up and excavated, to receive the full spread of the roots. A heap of rich loam or compost is laid in the centre, on which the tree is placed, and the roots are covered with the same, and watered, to consolidate the earth about the fibres. The other soil is then thrown on, and the turf returned to its place and beaten down firmly. Single trees should be staked; and if on a pasture, a cradle will be requisite to defend them from the browsing or rubbing of cattle.

Much has been written on the subject of transplanting *large* trees, and many successful exploits of this kind have been performed both in past and present times. Shady groves have been formed in the short space of a few months; proving that, with care, skill, and physical force properly directed, any tree of moderate size may be transplanted with safety and success. One precaution very much facilitates the execution: it is that of digging a circular trench at a proper distance, say six feet, round the trunk, and deep enough to be below, and to cut through all the roots except three or four of the largest, which are left at equal distances to act as spurs for the better security of the tree when placed in its new situation. The trench, after the stumps of the roots are cut smoothly off, is filled with prepared compost, for a new fringe of roots to strike into, and after one or two years, the tree is in a condition for removal.* In doing this, a deeper trench is made on the outside of the first, into which the mould from among the roots is drawn, until the whole are loosened from the soil; the spur-roots are also followed out and laid bare. The method of raising the tree by a machine is mentioned below. In replanting, much depends on laying out the roots, and firmly imbedding them in moistened earth, and also adding a pretty heavy covering of soil round the stem, to keep the tree steady against wind.

A machine for transplanting has been long in use,

* The renovation of decayed trees is effected in a similar manner.

on the principle of the common timber-truck—being a strong lever attached to the axle-tree of a pair of wheels. The latter are strongly constructed. The axle-tree is correspondingly substantial, and to its middle the pole or lever is securely fixed. The pole should be made of the best ash, seven inches square, with the edges planed off, and somewhat reduced in thickness towards the end. The length should be at least ten feet, for the longer it is, the greater the purchase in raising a tree. The pole is strengthened by side-braces let into the axle, and mounted with an iron eye and ring at the point. When used, it is backed against the tree, and the pole is raised and made fast thereto, as here represented. The wheels rest in the hollow made by baring and loosening the roots; and when all is ready, the strength of men, or that of a horse, is applied to the pole-chain, which is, together with the tree, pulled to the ground, the root being lifted out of the soil; and, when thus borne on the machine, it is drawn away, root foremost, to its new place, previously prepared for its reception. The wheels are drawn into the new opening, the pole and tree are set at liberty, and if the root be heavy, the tree will resume its former position with but very little assistance. The machine is then loosened from the tree, and removed; the roots are laid out carefully, and imbedded in loose soil, and the whole is finished by a copious watering.



When a machine is made on purpose for removing large trees, the axle-tree may be made to fit a pair of cart-wheels for a temporary purpose; but the axle should be formed with *straight*, not *drooping* ends, as they are usually made, because this facilitates the raising of the pole. Upon the upper side of the axle there should be a thick block of wood bolted, to give more elevation to the root when drawn along; and on this an old sack, or a thick band of straw, is bound, to prevent chafing the bark of the tree.

Many improvements in the apparatus used for transplanting have been introduced of late years, one of the most important of which is that of Mr M'Glashen (patented), by which he is enabled to lift trees of any dimensions. It consists of a number of large spades so arranged as to enter the soil around the tree, and raise it with an attached ball of earth, so that the roots are not disturbed, those extending beyond the ball being cut through. By a peculiar construction of carriage, &c., the ball of earth can be boxed up, and conveyed to any distance without separating from the roots. Mr M'Nab, of the Edinburgh Botanic Garden, has also introduced a system of transplanting, which has been long in use in the Botanic Garden, and is fully described in the *Scottish Gardener* and *Gardeners' Chronicle*. This method is not restricted to trees, but is also applicable to the re-tubbing of palms and other unwieldy plants, the same apparatus being available for both purposes. The many improvements that have of late years been introduced in the disposition of the trees and shrubs in the Botanic Garden, have been effected by means of Mr M'Nab's system.

Coppice—Live-fences.

Coppice or underwood is either natural or planted. Natural underwoods are often the remains of ancient forests which are kept enclosed, and are felled periodically at long or short intervals, according to the purpose for which their produce is to be applied.

Thriving and well-fenced and well-managed coppice is in some cases more profitable than timber-woods. Timber and coppice may be united; the standard trees to stand thinly, and if kept pruned up, the undergrowth is not much hurt by their shade. Mixed underwoods are cut every five, seven, or ten years, unless they are entirely of oak, when they are allowed to stand longer, for the sake of having larger poles, together with the bark, which last is a principal part of their value. On the subject of oak-coppice, Mr Brown remarks, that the value of the bark has fallen so much of late years, as to render the exclusive growth of this kind of underwood no longer a source of real profit. 'About twenty-five years ago the price of oak-bark was £16 per ton; while this year (1847) the highest price that has been given in Edinburgh is £5, 10*s*.*—making its value at the present time only about one-third of what it was twenty-five years ago, and consequently reducing the value of oak-coppice plantations in the same ratio; and upon this consideration, I do think that proprietors should not, at the present time, rear up oak-plantations with the intention of converting them into coppice, as has in many instances been done of late. I have seen plantations of healthy oak-trees, about thirty-five years of age, cut down for the sake of the bark they produced, and with the view of converting them into coppice-wood, so as to have a crop of bark every twenty-five years afterwards. Now, had those trees which were cut down at thirty-five years of age, been allowed to grow for other forty or fifty years, they would of course have attained their full magnitude, and been worth to the proprietor, at the end of that period, more than three times the money that he could get as the produce of the same plants if cut down and disposed of in the form of coppice-wood at periods of twenty-five or thirty years. No doubt, where old plantations are cut down, it is right and proper that the stocks of them should be converted into coppice-wood, for this is taking advantage of growths which can be converted into use, and which would otherwise be lost; but to raise up trees to a certain age, and then cut them down prematurely for the sake of their bark, is at best an enormous loss to the proprietor as well as to the country in general.'

For live-fences, except in peculiarly bleak and barren situations, hawthorn is the best adapted; care, however, is required both in the planting and trimming. There is a general complaint that thorn-hedges do not thrive well; but in most cases the want of success will be found to arise from improper treatment. The preparation of the land for planting hedges requires the greatest care, for if this be not cleared of weeds before the thorns are planted, it will be almost impossible to do it afterwards. Foul land should be well fallowed before the hedge is planted; and if poor, it will require to be manured. Old pasture-land should be pared and burned, and the ground otherwise well prepared for the reception of the hedge. If possible, the ground should be trenched to about eighteen inches deep, and four feet in breadth, the surface-soil being placed in the bottom of the trench; and this will be found an excellent way of getting rid of weeds. The expense attending a thorough preparation of the soil will be amply repaid

* Returns now before us from foresters in different parts of the country, shew the prices at the time we write (April 1857) to vary from £5, 5*s*. to £6, 15*s*. per ton; so that the price seems rather to have increased than otherwise since the date of Mr Brown's calculation.

by having a clean and well-growing hedge, which is a great ornament to an estate. Indeed, so convinced are most landed proprietors of the advantages of a thorough preparation, that the soil is now not only cleaned and trenched, but supplied with a compost of lime and ditch-clearings—a treatment which immensely facilitates the growth of the thorns at the most critical period of their existence.

The season for planting depends in some measure on the nature of the ground; for if this be very dry, the planting should take place in the autumn, or early in spring, in order that the plants may have made some root before the heat of summer sets in. The autumn is recommended by some as the best season for planting on all soils, and the month of February by others; but perhaps it is immaterial which period be chosen. If spring is the time fixed upon, it should be as early as possible, so that the plants may not have made progress in vegetation before transplanting. There are various modes of planting hedges, some preferring the even ground, others forming a mound, with a ditch at one side, and planting either at the top or on a shelf in the side of the mound; others, again, making a ditch on each side of the mound. If the land be good and dry, the hawthorn will grow quite well upon the level ground; but if the soil be of a wet nature, either one or two ditches will be required. The thorns should be planted at the distance of about three or four inches apart, and about the same depth as they stood in the seed-bed. The plants should then be covered with the finest mould, the points little more than projecting from the front of the mound. A wooden fence may be required to protect the young hedge until it has acquired size.

After being planted, the hedge should be carefully gone over two or three times a year, to cut up weeds. This operation must be performed until the plants have reached some height, and the weeds are completely eradicated, after which the usual cleaning at the roots once a year will be quite sufficient. The plants should never be cut till after three years old, for if cut when younger, the hedge becomes stunted, and is never so healthy. Hedges, when properly established, should be regularly pruned once a year.

When hedges get bare and thin at the bottom, they ought either to be cut over by the root, or to have their sides dressed up close to the principal stems. There is another method of repairing thorn-hedges, which is called *plashing*. It consists in cutting half through the stems adjoining the gap to be repaired, and then bending the upper portion over the vacancy, fastening them down by stakes, or by warping them into each other. By this means a live-hedge is formed more speedily than by planting young shoots, and more effectually than by inserting dead branches. The bent stems soon send out shoots; and if the plashing has been done with care, and that on moderately young and pliant branches, it will be found to be a cheap system, but not permanently efficient.

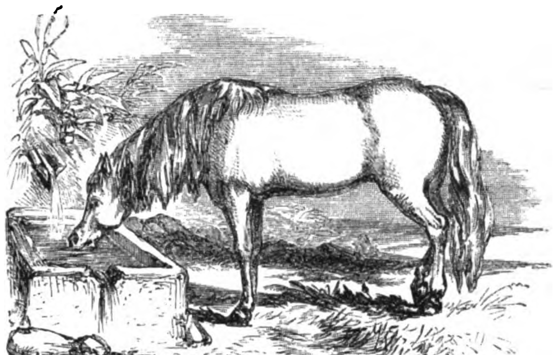
When thorn-hedges are cut too close by the ground, the decayed stocks should not only be taken out, but the earth where the stocks stood should be replaced with good fresh soil. The thorn-plants intended for filling up blanks should be carefully selected from such as have been transplanted two or three years, have stood thin in the nursery-bed, are well rooted, and free growers.

In high exposed situations, having thin moorish soils, or on hilly land composed of decomposed granite, thorn-hedges are seldom if ever found to thrive. In such situations, the beech has proved itself superior to every other plant, either as an assistant or a substitute for thorns. It retains possession of the soil, and continues to thrive when thorns decay or die out; and when regularly and judiciously cropped, it forms a compact fence, which few animals will attempt to break through. Indeed, experience has proved that, as a hedge-plant, the beech will thrive in any climate or soil; and what is of essential importance, it retains its leaves during winter, giving a genial warmth and shelter, besides being highly ornamental.

A very durable hedge for high situations with a light soil, may be formed by an admixture of thorn and beech plants in the proportion of two of the former to one of the latter. Such a fence not only looks well, but lasts well, if trimmed with due care and regularity. Latterly, furze or whins have been employed with advantage as fences. Many other shrubs and trees are used in live-fencing. Among the most common of these are the holly, the privet, and the yew, all of which bear pruning and training almost to any degree.

In maritime situations, where shelter is most wanted, such hedge-plants as the hawthorn and beech do not succeed; but the sea-buckthorn (*Hippophäe rhamnoides*) forms an admirable substitute. When well cared for, it may be trained into a neat and effective hedge, and does not suffer from the sea-breeze, even in the most exposed situations. The plane has also been recommended as a sea-side hedge-plant, but is inferior to buckthorn.

Cedars of Lebanon.



THE HORSE.

THE horse is universally acknowledged to be one of the noblest members of the Animal Kingdom. Possessing the finest symmetry, and unencumbered by those external appendages which characterise many of the larger quadrupeds, his frame is a perfect model of elegance and concentrated energy. Highly sensitive, yet exceedingly tractable, proud, yet persevering, naturally of a roaming disposition, yet readily accommodating himself to domestic conditions, he has been one of the most valuable aids to human civilisation—associating with man in all phases of his progress, from the temporary tent to the permanent city.

In ordinary systems of zoology, the horse is classed with the *Pachyderms*, or thick-skinned animals—as the elephant, tapir, hog, hippopotamus, and rhinoceros. Differing from the rest of the class in many respects, he has been taken as the representative of a distinct family, known by the name of *Equidæ* (*equus*, a horse), which embraces the horse, ass, zebra, quagga, onager, and dzegguetai. All these animals have solid hoofs, are destitute of horns, have moderately sized ears, are less or more furnished with manes, and have their tails either partially or entirely covered with long hair. The family may, with little impropriety, be divided into two sections—the one comprehending the horse with its varieties, and the other the ass, zebra, and remaining members. In the former, the tail is adorned with long flowing hair, the mane is also long and flowing, and the fetlocks are bushy; the latter have the tail only tipped with long hair, the mane erect, and the legs smooth and naked. The colours of the horse have a tendency to *dapple*—that is, to arrange themselves in rounded spots on a common ground; in the ass, zebra, and other genera, the colours are disposed in stripes or bands more or less parallel.

By his physical structure, the horse is fitted for dry open plains that yield a short sweet herbage. His hoof is not adapted to the swamp; and though he may occasionally be seen browsing on tender shoots, yet he could subsist neither in the jungle nor in the forest. His lips and teeth, however, are admirably formed for cropping the shortest grass, and thus he luxuriates where many other herbivorous animals would starve, provided he be supplied with water, of which he is at all times a liberal drinker. Delighting in the river-plain and open glade—the savannas of America, the steppes of Asia, and the plains of Europe, must be regarded as his head-quarters in a wild state. There is doubt expressed, however, as to the original locality of the horse. The wild herds of America are looked upon as the descendants of Spanish breeds, imported by the first conquerors of that continent; those of the Ukraine, in Europe, are said to be the progeny of Russian horses abandoned after the siege of Azov in 1696; and even those of Tatary are regarded as coming from a more southern stock. Naturalists, therefore, look to the countries bordering on Egypt as in all likelihood the primitive place of residence of this noble animal; and it is generally believed that the Arabian breed, when perfectly pure, presents the finest specimen of a horse in symmetry, docility, and courage. Regarding the horse as of Asiatic origin, we now find him associated with man in almost every region of the habitable globe. Like the dog, ox, sheep, and a few others of the brute creation, he seems capable of accommodating himself to very different conditions; and assumes a shaggy coat or a sleek skin, a size little inferior to that of the elephant, or not larger than that of an English mastiff, just as circumstances of climate and food require.

In a state of nature, the horse loves to herd with his fellows; and droves of from 400 to 500, or even double that number, are not unfrequently seen, if the range be wide and fertile. The members of these vast droves are inoffensive in their habits, and when not startled or hunted, are rather playful and frolicsome; now scouring the plain in groups for mere amusement, now suddenly stopping, pawing the soil, then snorting, and off straight as an arrow, or wheeling in circles, making the ground shake with their wild merriment. It is impossible to conceive a more animated picture than a group of wild-horses at play. Their fine figures are thrown into a thousand attitudes; and as they rear, curvet, dilate the nostril, paw in quivering nervousness to begin the race, or speed away with erect mane and flowing tail, they present forms of life and energy which the painter may strive in vain to imitate. They seldom shift their stations, unless compelled by failure of pasture or water; and thus they acquire a boldness and confidence in their haunts which it is rather unsafe to disturb. They never attack other animals, however, but always act upon the defensive. Having pastured, they retire either to the confines of the forest, or to some elevated portion of the plain, and recline on the sward, or hang listlessly on their legs

for hours together. One or more of their number are always awake, to keep watch while the rest are asleep, and to warn them of approaching danger, which is done by snorting loudly, or neighing. Upon this signal, the whole troop start to their feet, and either reconnoitre the enemy, or fly off with the swiftness of the wind, followed by the sentinel and by the older stallions. They are seldom to be taken by surprise; but if attacked, the assailant rarely comes off victorious, for the whole troop unite in defence of their comrades, and either tear him to pieces with their teeth, or kick him to death.

There is a remarkable difference in the dispositions of the Asiatic and South American wild-horses. Those of the former continent can never be properly tamed, unless when very young, but frequently break out into violent fits of rage in after-life, exhibiting every mark of natural wildness; while those of America can be brought to perfect obedience, and even rendered somewhat docile, within a few weeks, or even days. It is difficult to account for this difference in temper, unless we suppose that it is caused by climate, or rather by the transmission of domesticated peculiarities from the original Spanish stock.

SUBJUGATION AND DOMESTICATION.

As in South America we have the most numerous herds, and the most extensive plains for their pasture, so it is there that the catching and subduing of the wild-horse present one of the most daring and exciting engagements. If an additional horse is wanted, a wild one is either hunted down with the assistance of a trained animal and the *lasso*, or a herd are driven into a *corral*—a space enclosed with rough posts—and one selected from the number. The latter mode is spiritedly described by Miers, whose account we transcribe, premising that a lasso is a strong plaited thong, about forty feet in length, rendered supple by grease, and having a noose at the end: 'The corral was quite full of horses, most of which were young ones, about two or three years old. The chief guacho—native inhabitants of the plains are called peons or guachos—mounted on a strong steady animal, rode into the enclosure, and threw his lasso over the neck of a young horse, and dragged him to the gate. For some time, he was very unwilling to leave his comrades; but the moment he was out of the corral, his first idea was to gallop off; however, a timely jerk of the lasso checked him in the most effectual way. The peons now ran after him on foot, and threw a lasso over his fore-legs, just above the fetlock, and twitching it, they pulled his legs from under him so suddenly, that I really thought the fall he had got had killed him. In an instant, a guacho was seated on his head, and with his long knife cut off the whole of the mane, while another cut the hair from the end of his tail. This, they told me, was a mark that the horse had once been mounted. They then put a piece of hide in his mouth, to serve for a bit, and a strong hide-halter on his head. The guacho who was to mount, arranged his spurs, which were unusually long and sharp; and while two men held the horse by the ears, he put on the saddle, which he girthed extremely tight. He then caught hold of the animal's ear, and in an instant vaulted into the saddle, upon which the men who held the halter threw the end to the rider, and from that moment no one seemed to take any further notice of him. The horse instantly began to jump in a manner which made it very difficult for the rider to keep his seat, and quite different from the kick or plunge of our English steed: however, the guacho's spurs soon set him agoing, and off he galloped, doing everything in his power to throw his rider.

'Another horse was immediately brought from the corral, and so quick was the operation, that twelve guachos were mounted in a space which I think hardly exceeded an hour. It was wonderful to see the different manner in which different horses behaved. Some would actually scream while the guachos were girthing the saddle upon their backs; some would instantly lie down and roll upon it; while some would stand without being held, their legs stiff, and in unnatural positions, their necks half bent towards their tails, and looking vicious and obstinate; and I could not help thinking that I would not have mounted one of those for any reward that could be offered me, for they were invariably the most difficult to subdue.

'It was now curious to look around and see the guachos on the horizon in different directions, trying to bring their horses back to the corral, which is the most difficult part of their work; for the poor creatures had been so scared there, that they were unwilling to return to the place. It was amusing to see the antics of the horses; they were jumping and dancing in various ways, while the right arm of the guachos was seen flogging them. At last they brought the horses back, apparently subdued and broken in. The saddles and bridles were taken off, and the animals trotted towards the corral, neighing to one another.'

To hunt down the horse in the open plain requires still greater address, and greater strength of arm. According to Captain Hall, the guacho first mounts a steed which has been accustomed to the sport, and gallops him over the plain in the direction of the wild herd, and circling round, endeavours to get close to such a one as he thinks will answer his purpose. As soon as he has approached sufficiently near, the lasso is thrown round the two hind-legs, and as the guacho rides a little on one side, the jerk pulls the entangled horse's feet laterally, so as to throw him on his side, without endangering his knees or his face. Before the horse can recover the shock, the hunter dismounts, and snatching his *poncho*, or cloak, from his shoulders, wraps it round the prostrate animal's head. He then forces into his mouth one of the powerful bridles of the country, straps a saddle on his back, and bestriding him, removes the poncho, upon which the astonished horse springs on his legs, and endeavours, by a thousand vain efforts, to disencumber himself of his new master, who sits composedly on his back, and by a discipline which never fails, reduces the animal to such complete obedience, that he is soon trained to lend his whole speed and strength to the capture of his companions.

The subduing of wild specimens in America, the Ukraine, Tatary, and other regions, must be regarded as merely supplementary to that domestication which the horse has undergone from the remotest antiquity. A wild adult may be subjugated, but can never be thoroughly trained; even the foal of a wild mother, though taught with the greatest care from the day of its birth, is found to be inferior to domestic progeny in point of steadiness and intelligence. Parents, it would seem, transmit to their offspring mental susceptibility as well as corporeal symmetry; and thus, to form a just estimate of equine qualities, we must look to the domesticated breeds of civilised nations. At what period the horse was first subjected to the purposes of man, we have no authentic record. Trimmed and decorated chargers appear on Egyptian monuments more than four thousand years old; and on sculptures equally, if not more ancient, along the banks of the Euphrates. One of the oldest books of Scripture contains the most powerful description of the war-horse; Joseph gave the Egyptians bread in exchange for horses; and the people of Israel are said to have gone out under Joshua against hosts armed with 'horses and chariots very many.' At a later date, Solomon is said to have obtained 'horses out of Egypt, and out of all lands,' and to have had 'four thousand stalls for horses and chariots, and twelve thousand horsemen.' Thus we find that in the plains of the Euphrates, Nile, and Jordan, the horse was early the associate of man, bearing him with rapidity from place to place, and aiding in the carnage and tumult

of battle. He does not appear, however, to have been employed in the useful arts of agriculture and commerce; these supposed drudgeries being imposed on the more patient ox, ass, and camel. Even in refined Greece and Rome, he was merely yoked to the war-chariot, placed under the saddle of the soldier, or trained for the race-course.

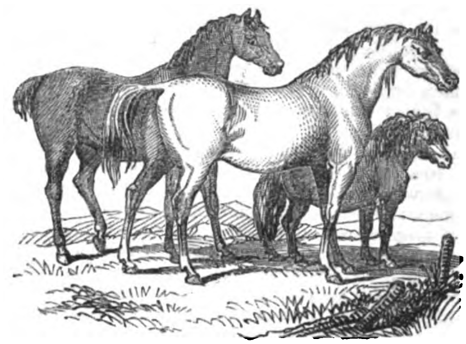
As civilisation spread westward over Europe, the demands upon the strength and endurance of the horse were multiplied, and in time he was called upon to lend his shoulder indiscriminately to the carriage and wagon, to the mill, plough, and other implements of husbandry. It is in this servant-of-all-work capacity that we must now regard him; and certainly a more docile, steady, and willing assistant it would be impossible to find. But it is evident that the ponderous shoulder and firm step necessary for the wagon would not be exactly the thing for the mail-coach; nor would the slow and steady draught, so valuable in the plough, be any recommendation to the hunter or roadster. For these varied purposes, men have selected different stocks, which either exist naturally, or have been produced by a long-continued and careful system of breeding. In a state of nature, the horse assumes various qualities in point of symmetry, size, strength, and fleetness, according to the conditions of soil, food, and climate which he enjoys. It is thus that we have the Arabian, Tatar, Ukraine, Shetland, and other stocks, each differing so widely from the others, that the merest novice could not possibly confound them. Besides these primitive stocks, a thousand *breeds*, as they are called, have been produced by domestication, so that at the present time it would require volumes even for their enumeration. In our own country, for example, we have such breeds as the Flanders, Norman, Cleveland, Suffolk, Galloway, Clydesdale, and Shetland; and of these numerous varieties, more especially adapted for the turf, the road, the cart, or the carriage. All this exhibits the wonderful docility of the horse, and proves how admirably he is adapted to be the companion and assistant of man, as the latter spreads himself over the tenantable regions of the globe. It is to the character, training, and management of the horse thus domesticated that we devote the following pages.

DOMESTICATED VARIETIES.

Horses exist, as we have said, in numerous varieties, distinguishable by size, strength, colour, and other qualifications, the result, most likely, of peculiarities of climate, food, and artificial treatment. The following is a brief notice of the leading varieties or breeds now common in Britain:

The Arabian.

The Arabian horse is considered to occupy the highest rank among the numerous cultivated varieties, and embodies that qualification in its purest condition, known by the term *thorough-bred*. The pure Arabians are somewhat smaller than our race-horses, seldom exceeding fourteen hands two inches in height. Their heads are very beautiful, clean, and wide between the jaws; the forehead is broad and square; the face flat; the muzzle short and fine; the eyes prominent and brilliant; the ears small and handsome; the nostrils large and open; the skin of the head thin, through which may be distinctly traced the whole veins of the head. The body may, as a whole, be considered too light, and the breast rather narrow; but behind the arms, the chest generally swells out greatly, leaving ample room for the lungs to play. The shoulder is superior to that of any other breed; the scapulæ, or shoulder-blades, incline backwards, nearly in an angle of 45°; the withers are high and arched; the neck beautifully curved, and the mane and tail long, thin, and flowing; the legs are fine, thin, and wiry, with the pasterns placed somewhat oblique, which has led some to suppose that the strength was thereby lessened, which is by no means the case; the bone is of uncommon density, and the prominent muscles of the forearm and thigh prove that the Arabian is fully equal to all that has been said of his physical powers.



English Hunter—Arabian—Shetland Pony.

The Arabs of the Desert have made the breeding of horses their sole occupation for ages bygone; and from their strict attention to certain rules, they may be justly regarded as the first breeders in the world. They take infinite trouble in grooming their steeds, and are extremely regular in their hours of feeding them morning and evening. They get but little drink, and that is supplied to them two or three times a day; they conceive that much water not only destroys their shape, but also affects their breathing. In spring, they are pastured on dry aromatic herbage; and during the rest of the year they are fed on barley, with a small quantity of straw; and they are the hardiest horses in the world. The Arab trains his horse by kindness, and never on any occasion strikes it; the consequence is, that the animal shews a degree of affection and tractability in which most British horses are quite deficient. The pure Arab horse is employed only for riding, and possesses great fleetness.

The following interesting account of the hardihood of the Arabian is given by M. Chateaubriand, in his travels in Greece: 'They are never put under shelter, but left exposed to the most intense heat of the sun, tied by all four legs to stakes driven in the ground, so that they cannot stir. The saddle is now taken from their backs. They frequently drink but once, and have only one feed of barley in twenty-four hours. This rigid treatment, so far from wearing them out, gives them sobriety and speed. I have often admired an Arabian steed thus tied down to the burning sands, his hair loosely flowing, his head bowed between his legs, to find a little shade, and stealing with his wild eye an oblique glance of his master. Release his legs from the shackles, spring upon his back, and he will "paw in the valley, he will rejoice in his strength, he will swallow the ground in the fierceness of his rage;" and you recognise the original picture as drawn by Job.'

The Arabs are exceedingly particular regarding the pedigree of their horses; and they have amongst them a breed which they declare has descended from a horse of King Solomon. It must not, however, be supposed that all the horses of that country are of the finer kinds; for the Arabs have three distinct breeds; the two inferior kinds, they allege, were introduced from India and Greece. The superior kinds they call nobles; and they are never sold without a pedigree, which is most scrupulously attended to.

The British Racer.

The British race-horse is a cultivated breed, originally sprung from the Arabian, and to which is traced the quality of being *thorough-bred*. The skins of race-horses

are delicate, with short hair, usually tending to the bright-brown or bay generally characteristic of the horses of the East, and sometimes to the gray, prevalent likewise among the Arabs and Barbs. They are frequently chestnut, which may be looked upon as a mixture of the dun or tan colour of some of the races of Northern Europe with the finer brown or bay; and sometimes, though very rarely, they are of the bright-black common to the great horses of the plains of Germany. They are of medium height, rarely exceeding fifteen hands. Their form is that which an almost exclusive attention to the property of speed has tended to produce. They have the broad forehead, the brilliant eyes, the delicate muzzle, the expanded nostrils, and the wide throat, characteristic of their Eastern progenitors. Their light body is comparatively long, and suited to the extended stride. Their chest is deep, so as to give due space to the lungs, but comparatively narrow, preventing the fore extremities from being overloaded, and the limbs from being thrown too far asunder in the gallop. Their shoulder is oblique, to give freedom of motion to the humerus; and their haunch is long and deep, beyond that of any other known race of horses, indicating the length of those bones of the hinder extremities on which the power of progression essentially depends. Their limbs are long and muscular to the knee and hock, and below, tendinous and delicate; and their pasterns being long and oblique, give elasticity to the limbs.

The pedigree of race-horses is always a matter of consequence to the breeder and purchaser of these animals, and is preserved with the same degree of care as the genealogy of many a noble family. By jockeys and others, therefore, a list or stud-book is kept of the sires and dams of their horses, which can be exhibited if required. The pedigree of many fine racers of the present day is traced through stud-books to the Darley Arabian—a horse purchased by a Mr Darley at Aleppo, from which it was imported to England. One of its immediate descendants was the celebrated Flying Childers, bred by Mr Childers of Carr House. This beautiful racer is reputed to have been the fleetest runner ever known in England, or perhaps in the world. On one occasion he ran (carrying nine stones two pounds) round the course at Newmarket—which measures three miles, six furlongs, and ninety-three yards—in six minutes and forty seconds.

Horse-racing is essentially an English sport, with its head-quarters at Newmarket, Epsom, and Doncaster. Many object to it as cruelly taxing the strength of a noble animal; but when the distances to be run are not too great, and where steeple-chasing is prohibited, the race becomes a legitimate test of fleetness, courage, and endurance. An animal that has repeatedly beaten a host of competitors, must possess superior qualities, rendering him of the utmost value for breeding purposes—and these qualities, especially we repeat of speed, spirit, and endurance, are, we believe, best brought out by racing, judiciously and humanely regulated. Unfortunately the sport is too often mixed up with dissipation, fraud, and gambling.

Hunters, Coach-horses, Hackneys.

The hunter is a combination of the thorough-bred race-horse and half-bred horses of greater strength and bone; but changes are continually taking place in its character. The older race of hunters has been giving place to one of lighter form and higher breeding, and even the thorough-bred horse is now employed by numerous sportsmen. In his improved state, the hunter may rank as a saddle-horse of the first class, combining strength with fleetness. The prime qualities of a hunter may be briefly summed up—head small, neck thin, crest firm and arched, a light mouth, broad chest, body short and compact, the hocks well bent, power behind to push him over difficulties, and broad well-made feet turned outward. He is prepared for his duties by physic, air, and exercise. To do him justice, the hunter should not work above three days a week; and after a hard day's run, he ought certainly to have two or three days of rest. The charger or cavalry-horse partakes of the qualities of the hunter—great strength and spirit, without which he would be unable to endure the toil of warfare in a rough country.

The better kind of coach-horses owe their origin to the Cleveland bay, and are principally bred in Yorkshire, Durham, and the southern districts of Northumberland; and some few have been produced in Lincolnshire. The coach-horse is produced by a cross of the Cleveland mare with a three-fourth or thorough-bred horse, which is possessed of sufficient substance and height. The produce of these is the coach-horse of the highest repute, and most likely to possess good action. His points are advantageously placed, with a deep and well-proportioned body, strong and clean bone under the knee, and his feet open, sound, and tough. He possesses a fine knee-action, lifts his feet high, which gives an elegance to his paces and action: he carries his head well, and has a fine elevated crest. The full-sized coach-horse is, in fact, only an overgrown hunter, too large for that sport. Before the days of railways, the carriage-horse, reduced to drawing stage-coaches, was often used in a very disgraceful manner. Urged with a heavy draught to the height of his speed, almost incessantly wrought, whipped unmercifully, and poorly groomed, his fate was melancholy in the extreme. It ought to be recollected, that in proportion as the load or draught is increased, so is the animal's power of speed lessened; and therefore to make him both draw a heavy weight and run also, is to put him beyond his natural powers, and his muscular energy suffers accordingly. We shall afterwards advert to the principles which ought to regulate both draught and speed.

The term *Hackney*, in common use, is employed to denote a kind of horse fitted for general services, and is therefore understood to exclude the horses of the highest breeding, as the thorough-bred horse and hunter; and there is further associated with the idea of a hackney, an animal of moderate size, not exceeding fifteen hands, and possessing action, strength, and temper. Our present breed of hackneys have a considerable portion of racing blood in them, varying from a half to seven-eighths. The latter are too highly bred for the general purpose of a roadster, as their legs and feet are rather tender; and their long paces and straight-kneed action are ill adapted for the road, being more fitted for cantering and running than the trot, which is the distinguishing characteristic of a good hackney. Indeed, they should never be permitted to go at any other pace than a trot, which is undoubtedly much better adapted for the road than cantering.

Nothing is more essential in a hackney than sound strong fore-legs, and also well-formed hind ones; his feet must be quite sound, and free from corns, to which hard-ridden horses are very liable; and he ought only to lift his fore-legs moderately high. Some are of opinion that he cannot lift them too high, and conceive, while he is possessed of this quality, he never will come down. There is a medium, however, in this, as a horse that raises his fore-legs too high in trotting is always disagreeable in his action, which greatly shakes and fatigues the rider; besides, he batters his hoofs to pieces in a few years. The principal thing to be attended to is the manner in which the hackney puts his feet to the ground; for if his toes first touch the road, he is sure to be a stumbler. The foot should come flat down on the whole sole at once, otherwise the horse is not to be depended upon in his trotting. A hackney should be particularly even-tempered, and not given to starting. The thorough-bred hackney ought to possess two qualities, indispensable to the safety of the rider—he should never shy at anything on

the road, and his motion at a trot should be much more smooth than that of a half-bred horse.

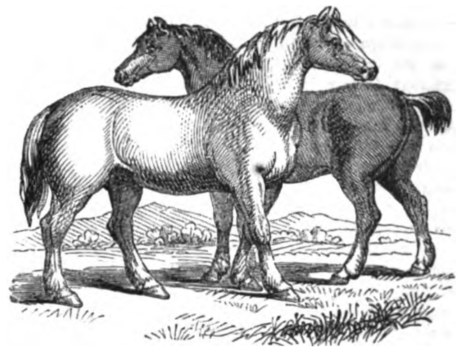
The proper kind of saddle-horse is only a variety of the hunter, possessing less or more breeding, according to the nature of the work required of him, and the taste of the breeder. Of the great varieties of saddle-horses, there may be said to be a chain of connection, as respects spirit and form, from the racer to the cart-horse; and therefore the station which any individual occupies is almost undefinable. The saddle-horses of England are celebrated for their beauty and action; and nowhere are seen so many of elegant forms as in London. Latterly, the breeds have been tending to greater lightness, the state of the roads not now requiring the weight and substance which was at one time necessary.

The Cart or Draught Horse.

The cart-horses of Great Britain are extremely variable in point of size as well as in shape, differing in almost every county. One principal character, however, is weight, to give more physical force in the draught. They should not be above sixteen hands high, with a light well-shaped head and neck, short pointed ears, with brisk sparkling eyes; their chests should be full and deep, with large and strong shoulders, well-raised withers, and deep wide chest. The back should be straight, and rather short, the ribs well arched, and the space between the last rib and the haunch-bone short. A long-carcassed, flat-ribbed horse tires easily, eats voraciously, and thrives badly. The limbs, strong, flat, and muscular, and well placed under the body, should not be disfigured by too much hair—a very common fault in the heavier English horses. The joints should be large and pliant, the feet wide, tough, and sound; and with limbs and feet such as these, the cart-horse will be able to walk easily four miles an hour, or plough his acre daily. For ordinary farm-work, we prefer strong-boned, clean-limbed horses with some breeding, and with the activity and courage which accompanies breeding, to the coarser, heavier, more sluggish race still too prevalent.

In the midland counties of England—Warwickshire, Derbyshire, Leicestershire, Lincolnshire, and Nottinghamshire—there is a very large breed, called the great cart-horse. It was bred in the lowland rich alluvial pastures of the plains of these counties, from the Flemish and Dutch horses with the larger English breed. Mr Bakewell introduced horses, and also mares, from the Netherlands, and thus produced those fine animals with Belgic blood both on the side of the sire and dam. The very large horses of seventeen hands and upwards are only useful for the purposes of brewers' drays, wagons, and the slop-carts of London. It is, however, doubted if they answer the better for their gigantic size; and all who have written on the subject, consider that they are inferior in point of strength, on account of their bulk; for by the feeding which is required to increase their dimensions, little of muscular fibre is produced, the growth being principally in the cellular tissue and fat; and the additional quantity of food required to keep up their system, must more than counterbalance any advantage to be reaped from their size.

Latterly, considerable pains have been taken to improve the qualities of ordinary cart-horses, among which we include those required in agriculture. A breed called the Clydesdale is highly valued for either cart or plough. Animals of the Clydesdale breed reach to a large size, and are not unfrequently to be met with sixteen and a half hands high. These animals are strong and hardy, but their heads are somewhat coarse, and they are rather flat on the hinder quarters. The usual colour of these horses is gray or brown. This breed is supposed to have originated about one hundred and forty years ago, between the common Scotch mare and the Flanders horse. As a breed, the Clydesdale is rapidly rising in estimation, and is now extensively used.



Clydesdale Horse—Suffolk Punch.

Ponies.

A horse beneath thirteen hands is called a pony, but this definition is not very strictly attended to, and the same thing may be said of the *galloway*. The old Scottish galloways, which took their name from the district of Galloway, in the south-western extremity of the country, are now nearly extinct. They were stout, compact animals, sure-footed, and of great endurance, and on these accounts invaluable in travelling over rugged and mountainous districts. The beauty and speed of the galloway were supposed to have arisen from the breed having been the produce of the Spanish jennets that escaped from the wreck of the Spanish armada; and these, crossed with our Scottish horses, gave rise to this esteemed breed. But we apprehend they were famous at a date long prior to that event, as this district is known to have supplied Edward I. with great numbers of horses. This breed seldom exceeded fourteen hands in height: their colour was generally bright bay or brown, with black legs, small head and neck, and their legs peculiarly deep and clean. A compact, stout-built pony, of from thirteen to fourteen hands high, and possessing some of the qualifications of the galloway, is called a *cob*, which is valuable as a steady pacer, at an easy rate.

The small ponies of the Highlands of Scotland and Shetland (usually called *shelties*) may almost be termed wild animals; for they go at large in herds on the hills and wastes, and are not shod till caught and put into training. They are docile and tractable, and being very sure-footed, are the best adapted for boys' riding. The Welsh pony is more handsomely formed than that of Shetland; has a small head, high withers, deep round body, and excellent feet. The Exmoor and Dartmoor ponies are also a hardy sure-footed race, well adapted for riding in wild districts. The ponies of Norway and Sweden, which are of a dingy cream colour, and of which there are now occasional importations to Britain, are considerably larger than the Shetland or Welsh breeds, and are hardy, sure-footed, and docile.

REARING OF HORSES.

The breeding and rearing of horses are carried on professionally in England, chiefly in Yorkshire; but many private gentlemen and farmers also address themselves to it as a means of pecuniary profit and the improvement of their animal stock. We do not pretend here to offer any specific directions on this branch of our subject, it being one in which the public at large are not particularly interested; and a few observations seem all that is necessary.

The circumstance which the breeder of horses requires to keep most in mind is, that the qualities, good or bad, of the animal are hereditary. Finely made horses

produce finely made descendants, and *vice versâ:* heavy cart-horses never produce animals possessing the qualities of racers. Thus the bone, blood, and general make are directly transmissible; and, in the case of crossing, the produce is found to possess a proportional share of both sire and dam. Cross-breeding between extremely different horses is not found advantageous: it is a generally recognised principle, that the nearer the resemblance between the parents, so will the produce be more satisfactory. Mr Smith, in his *Observations on Breeding for the Turf*, remarks, that 'the stock of some mares will frequently partake most of the dam, and that of others, most of the sire; and sometimes one foal will partake most of the mare, and the next perhaps, most of the horse, &c. It also occasionally happens that the produce bears some resemblance to its grandsire, grandam, or other distant kindred; and although this does not perhaps often occur, so as to be very perceptible, yet as their qualities must, in a lesser or greater degree, descend to their progeny, it has always had its due weight; hence the value and partiality to blood, or ancestral excellences, transmitted through many generations.' He further observes, however, 'that he is disposed to attribute more in general to the dam than to the sire, inasmuch as he is decidedly of opinion that a good mare put to the worst thorough-bred horse would be much more likely to produce a runner, than a bad mare put to the most fashionable stallion in England; and therefore a person possessing good mares may bring any stallion into repute.' The grand aim of the breeder must be the propagating of excellences, and avoiding defects; but this is not to be accomplished, as respects important alterations, all at once; improvements in this, as in everything else, being the work of time and a judicious experience. Breeding *in-and-in*, as it is called, or between close relationships, is decidedly pernicious, and should by all means be avoided.

The season for mares is about February and March, but in some cases it continues later; and the term of gestation is generally over eleven months. The foal remains with the mother till weaned, which takes place earlier or later, according to the quantity of milk, the strength of the animals, and the season of the year. On removal, it requires to be carefully attended to, and provided with soft nourishing diet. Few things contribute more to the health and perfection of young horses than a sweet, sound, and hard-bottomed pasture-range.

The operation of cutting is seldom performed on thorough-bred colts, but with all others it is common. It is an operation which ought by all means to be left to the veterinary surgeon or skilful farrier. The best authorities recommend it to take place with young cart-horses when four or five months old, but if for carriage or light work, it may very properly be postponed till the animal is twelve months old. The use of the operation is to render the horse more submissive than if left in an entire state, and to devote him altogether to the work he is required to perform. The advantages, whatever they are, are in some measure lessened by the lowering of spirit. The practice, however, is universally recognised in Britain, as one indispensable where numbers of horses are congregated, and required to be kept in good condition.

Breaking, or reducing the young animal to obedience, is a most important point in the education of the horse. If previously accustomed to handling, the difficulty of breaking will be much lessened. Racing-colts are now begun to be broken at one year old, and saddle-colts at two years, and are finally and fully broken and trained, some at three, and few later than four years old. Breaking horses is a regular business, and is best left to the person who is well accustomed to it, provided he follow a judicious course of treatment. As in the training of children, gentleness, with firmness, ought to be a prevailing principle of management. The chief apparatus of breaking is a powerful bridle or head-tackle, with boots or pads strapped on the legs, to prevent them knocking against each other. The young horse is to a certain extent trained before his back is mounted; all the preliminary part of the process of subduing being accomplished while he is led by the bitted tackle. His back is not to be mounted till he is evidently able to endure the load without injury to his figure: too early mounting is apt to make him hollow-backed for life. In putting on a saddle for the first time, great caution should be taken; let the girths be drawn loosely, the crupper smooth, and keep the stirrups from dangling. In short, the animal requires on this trying occasion to be treated with as much kindness as it is possible to employ.

Having, by the various means which are adopted, brought the animal into subjection, and in effect taught him that he must in future act the part of a dutiful servant to an indulgent but firm master, the next step is to teach him his paces. These are partly artificial. Commence with slow and regular walking; whenever he is inclined to bolt, bringing him back to the steady pace you desire. After he has been accustomed to slow paces on a methodic plan, go on to the slow trot, then the quick trot, and, lastly, the canter and gallop. By no means allow him to mix these paces—that is, half-canter and half-trot—which would be an ungainly hobble; but let him know that he must, for the time being, keep to one kind of pace. The skill of the breaker consists in enforcing these lessons, and teaching the animal to change readily and neatly from one pace to another by little more intimation than a twitch of the rein. Lawrence recommends that 'a graceful canter should be encouraged, commencing with the proper or off-leg foremost, and the nag accustomed to be pulled up from the canter to the trot without unseemly and unpleasant blundering. The lessons should not be too long or fatiguing, but the young animal kept in as cheerful and easy a state as possible.' The first shoeing ought to be performed with great care, so as to alarm the animal as little as possible.

In connection with the breeding of horses, we may say a few words respecting *mules*, or the hybrid offspring of the horse and ass. The mule proper is the produce of a male ass and mare; when the parents are the horse and she-ass, the produce is called a *hinny*. The mule is the superior animal, partaking to a larger degree in the qualities of the horse; it is more robust, plump, and hardy, and better adapted for all the ordinary purposes of riding and draught. The hinny is more thinly made, has a longer head, and is altogether more like the ass than the horse. Mules of both kinds live to a very old age, and when properly trained, they are tractable, and very serviceable animals. There are comparatively few mules in Britain; but in Spain, and some other countries of Southern Europe, also in Spanish America, they are numerous, and are used in carriages of people of the highest rank. According to a well-known principle in natural economy, by which intermixture of kindred species is not allowed to go beyond a single step, and only for one generation, mules do not usually breed; and the stock requires to be kept up by a recurrence to the common parentage.

The Teeth—Age.

The horse attains maturity at five years old, and he is in his prime till eight or nine. If no unfair play be used, his age may be judged of from his teeth, or, as it is called, *mark of mouth*. At five years old, when the teeth have been fully developed, the horse possesses six teeth in the front of each jaw, called the incisors or *nippers;* it is with these teeth that he bites. At a short distance from each end of the row of incisors, and in each jaw, there is a solitary canine tooth; these canine teeth are technically named *tushes*. At a greater

distance inward in each jaw, and on each side, there are six grinders—the whole apparatus being designed to bite or crop the herbage, to tear, and to chew. At five and a half years old, the nippers are marked by a natural cavity formed in the substance between the outer and inner walls, and it is the presence or absence of these darkish marks that certifies the age of the animal. When the horse reaches six years, the marks in the two front nippers in the nether jaw are filled up, and the tushes are blunted. At seven years, the two nippers next the middle ones are also filled up; at eight, the two outer ones are filled up also, and the tushes are round and shortened. The lower nipper teeth are now all smooth; the marks are gone; but in the teeth of the upper jaw, marks remain a year or two longer. At eight years, the disgraceful practice of *bishoping*—a term given from the name of the inventor—is often resorted to, for the purpose of imitating the obliterated marks. An engraving tool is employed to cut the surface, and a hot iron is then applied to give a permanent dark stain. This infamous trick may impose on the ignorant; but a person skilled in horses can easily detect the imposition, from the stains being diffused around the marks, which, moreover, are round instead of oval.

As a horse, if well treated, remains in excellent working condition till twelve years, and even later, the disappearance of the marks on the teeth is often of little consequence. Some horses are as valuable to their owners at fifteen years as they are at eight; and for ordinary saddle-work, ten to twelve may be considered an age sufficiently young. It is important, however, that the teeth are capable of mastication; for if the animal is unable to chew his food properly, he cannot be kept in good condition, or fit for the performance of his duties. In consequence of the very general abuse of horses, few live till twenty-five years old; and the instances of any living till above thirty are rare.

Technical Terms.

Horsemen employ terms to horses which are not strictly adhered to in ordinary language. A male horse left uncut is said to be an *entire horse*, to distinguish it from the *gelding* or cut animal. A female horse is always spoken of as a *mare*. A young male horse is called a *colt*, and a young female, a *filly*. *Thorough-bred*, as already noticed, is applied only to animals whose pedigree can be traced to an Arabian origin, without stain or any common intermixture. When the pedigree of the racer is to a certain degree stained, the animal is called a *cocktail*. The term *blood* is of more loose signification; but what is generally understood by it is a horse which is thorough-bred, or of the blood of the Arabian, and consequently shews a fine spirit and action. A horse may be half-bred, three parts bred, and so on, according to his pedigree. The half-bred is produced from a racer and a common mare. Some of the best riding-horses are of this stamp. The term *welter horse* is applied to racers which are able to carry the highest weight.

Horses are measured by *hands*, four inches being reckoned to the hand; the measure is taken from the highest point of the withers to the ground. To all the more prominent parts of the body and members, certain technical names are applied; for example, to take the four extremities first: the *muzzle* includes the lips, mouth, and nostrils; the *withers* are the sharp protuberance over the shoulders between the back and neck; the breast is the *counter;* the *arm* is the upper part of the fore-leg, but enveloped in the muscle of the shoulder; beneath it is the *forearm*, which is the higher part of the visible leg, and extends downward to the *knee;* below the knee we have another stretch called the *shank*, which extends to the *pastern*, or, as we might call it, the ankle; the *fetlock* is behind the pastern; beneath are the feet. A few of the hinder extremities are named as follows: the *croup*, which extends from the loins to the root of the tail or rump; the *flank*, extending from the ribs to the haunches; and the *leg* or thigh, which reaches down to the *hock* or middle joint of the hind-leg, corresponding to the knee in the fore-leg. The left side of a horse is called his *near* side; and his right, the *off* side.

The greater number of British horses are of a dark colour, inclining to black or brown, but of innumerable shades. One kind of brown is called bay, and another the chestnut; a yellowish chestnut is termed the sorrel. The roan is a blending of red and whitish tones. The gray is a mixture of white and black hairs, and in old age, becomes altogether white. The dark colours are the most esteemed for their physical qualities, and patches of white on the legs are considered defects or foul markings.

STABLE MANAGEMENT.

The horse, as has been already mentioned, possesses very delicate senses, and is nice in his habits, in which respect he differs very materially from black-cattle. In a state of nature, the animal seems to be best adapted for a mild and genial climate, and to rejoice in freedom and space. When reduced to domestication, care should be taken to violate as little as possible his natural tastes and habits. His delicacy of constitution, augmented in no small degree by an artificial mode of life, should warrant the best attentions of his keepers; and whatever be the nature of his work, he should be treated with kindness, regularly fed and supplied with pure water, allowed a cleanly and well-ventilated habitation, and his body and limbs preserved free from dirt and all offensive matter that may cling to them. The leading features of management may be defined as follows:

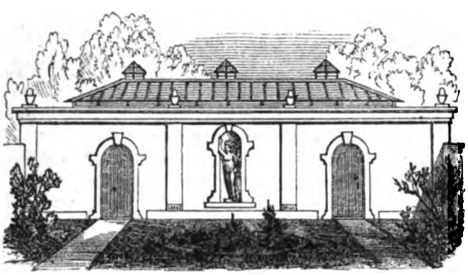
The Stable.

A high authority states it as his belief that nine-tenths of the diseases which afflict horses owe their origin to, or are greatly aggravated by, the defective arrangement and construction of stables. The chief points to be attended to are: the situation of the stable; its construction, so as to prevent damp and secure ventilation; its size; and its fittings and appendages. A stable should never be built in a marshy or hollow spot, but on a gentle declivity, so as to admit of good drainage, and with a southern exposure, in order to command good light—another important point. The first thing in the actual construction is how to secure dryness. The effects of damp on horses are immediately visible in languor, refusal of food, liability to colds and inflammation. Glanders and farcy, if not entirely owing to a humid atmosphere, as some hold, are certainly encouraged and fostered by it. The site of the stable, then, must be surrounded and intersected by smaller drains leading into a main-drain, with a good outfall. The walls again, whether of stones or brick, should be made *double*—the hollow space, in order to prevent the lodgment of rats, being not more than two inches wide. To provide against surface-water rising up the walls by capillary attraction, the first course above the ground may be covered with a coating of coal-tar and sand, or with sheet-lead. The roof should have a range of guttering completely round it, and the rain-water should be collected in a tank for use.

Damp *floors* are in so far provided against by thorough under-drainage; but a floor completely impervious to moisture from below may be had by constructing it of asphalt, or of flags set in cement, and with grooved surfaces. Good floors are also made of bricks set on edge, or of tiles with corrugated surfaces. To prevent the lodgment of the urine of the animals, the floors of the stalls should slope two or three inches in ten feet towards a channel running along behind the horses, which channel should itself have a slope towards the grating or gratings of the drain connected with the liquid-manure tank. These drains should be carefully

trapped. The slope of the stalls has no injurious or incommoding effects on the horse while reclining, as some have imagined. A dry stable-floor is effectually secured by the use of Forbes's drain-pavement, in which the flooring-bricks are grooved so as to form a system of channels for the urine.

The inside of the stalls should be boarded, and a lining of wood, four or five feet in depth, should be carried round the bottom of the other walls; all above should be plastered and white-washed.

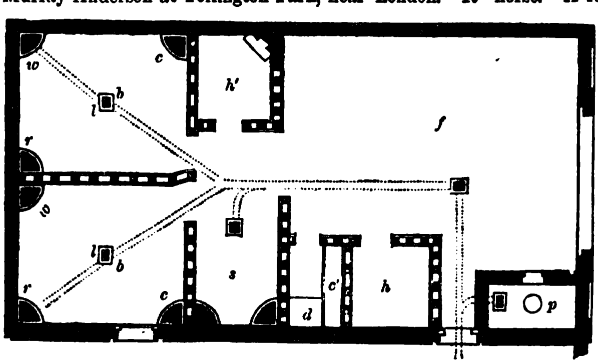


Elevation.

The evils of defective ventilation to animal life in general (see PRESERVATION OF HEALTH, also WARMING AND VENTILATION) are aggravated in the case of horses by the quantity of ammonia developed from the urine. This is less the case in stables where the floors are kept dry and sweet by the means above described; still, in every stable, means must be provided for the constant removal of tainted air, and the supply of fresh. The principles laid down in the number just referred to will be found applicable here.

A stable should never be large, as it is then liable to great fluctuations of temperature, according to the varying numbers in it at one time. A good size is one with ample room for six or eight horses. A stable with a row of stalls on one side only is better than one with double rows; if double, the space between should not be less than eight or ten feet. Sixteen feet is a proper width for a stable with a single row, ten feet being allowed for the depth of the stalls. Each stall is usually five and a half feet wide, but when space will permit, a width of six feet is advisable.

We give a ground-plan and elevation of what is considered by good judges a model stable, erected by Mr Murray Anderson at Tollington Park, near London. It



Ground-plan.

is planned to accommodate three horses, and contains coach-house and stable-yard under the same roof: *lb*, *lb* are two loose boxes, having each a rack for hay, *r*, a corn-box, *c*, and a water-trough, *w*; *s* is a stall five feet six by nine feet; *c'* is a corn-bin, and *d*, one for beans; *h* is a hay-shed; *h'*, the harness-room; *f*, the covered yard for cleaning carriages, &c.; *p*, the dung-pit, which is an air-tight tank, with a ventilating tube rising above the roof. The dung is thrown down by a trap-door inside, and removed by another outside. The building is lighted from the roof, which also contains three ventilators for the escape of the air. Fresh air is admitted by gratings at the bottom of the pillars represented in elevation; these being hollow, the air ascends, and enters the stable by similar gratings at the top inside. The whole structure, walls and floor, rests on concrete.

We have now to consider the fittings; and first as to *windows*. When we say that the stable should be well lighted, we certainly oppose one of the most vulgar prejudices respecting horse-management. In most instances, stables are kept as dark as dungeons, greatly to the injury and discomfort of the inmates. It is impossible to understand what can be rationally designed by keeping horses standing in the dark during their waking-hours. Nature never intended anything of the kind, and the practice should be abolished. The best way of lighting is from the roof, the windows being capable of being easily opened from below by means of cords and pulleys; which arrangement furnishes at the same time a means of ventilation. When lighted from the side-walls, Mr Stephens recommends the lower part of the window to be *dead*, the upper part only glazed, and capable of being opened. The stable should be entered by one door only, placed at the end of the building; it should be eight and a half feet high, and not less than five wide. It is advisable to have a spring by which it can be kept open until the horse is clear; when this is released, the door should be so hung as to close itself.

Hayloft—Racks—Mangers.

The hayloft, or place of deposit for hay, ought not, as is usually the case, to be over the stable, but adjacent; and a chamber level with the floor of the stable, and behind the stalls, is preferable, the hay being passed into the racks through doors opening from this chamber. In cases where haylofts are used, let them be kept as clean as possible, and allow no opening to the racks.

Hay-racks of the best material and form are made of iron, the bars rounded, and two inches from each other. The rack need not traverse the whole breadth of the stall, because in such a plan rubbish collects in the corners. A size to hold from a half to a whole stone of hay will be sufficient in most instances. A convenient form is that of a convex or bulged grating from the wall, placed a little above the head of the horse. A rack of this or any other shape cannot be kept too clean; the bars should be daily rubbed, and all refuse of hay removed. In improved racks, a drawer is provided, into which the *seeds* drop. A very ingenious and economical form has recently been introduced. It consists of a square iron casing, placed in the corner of the stall, the upper end being formed by a wide grating; a movable bottom slides up and down in the casing, being drawn up towards the top by a weight, which is sufficiently heavy to lift also the hay which is placed upon it. As the horse draws the hay through the top grating, the weight keeps it constantly pressed against it, so that he withdraws only a mouthful at a time, and is prevented from littering it about his stall. Mangers, for the supply of corn, &c., are now almost universally made of iron, with enamelled interiors; they are thus easily kept clean. They should be supplied through a spout regulated from the outside of the stall. Water is also provided now by an iron enamelled trough, to which it is supplied by a special water-pipe and tap, and withdrawn by means of a plug in the bottom leading to a waste-pipe.

Bedding—Cleaning.

The good horse sleeps in a lying posture, his legs being partly drawn under him, and his head remaining up. A horse that habitually sleeps standing, or will not lie down at night, is usually reckoned to be of little value; for it is indispensable to doing his duty during the day that he rests well at night. The preparation of a bed for the animal ought to be one of the most pleasing parts of a stable-keeper's duty, and he should perform it well. The best bed is made of wheat-straw; but when that is dear, or cannot be got, the straw of oats may suit the purpose. The more even and less rumpled the litter, the better. The bed should be made level, or sloping slightly from the sides and head towards the centre, and be completely free of hard lumps. All ought to be smooth, clean, soft, and the depth of litter perhaps seven or eight inches. Every morning, the soiled litter is to be taken away to the dung-yard, and the clean portion separated and placed at the head of the stall, or in some other convenient situation, ready to be employed again at night. The stable should be clean swept, brushed, and thoroughly ventilated every morning, leaving impurities neither on the ground nor in the atmosphere.

Stable Furniture—Stablemen.

Every stable is to be provided with proper receptacles for hay and straw. The oats, peas, beans, bran, &c., should be kept in one large chest with divisions, or separate chests, and, if possible, be placed in an apartment separate from the stable. For small stables, an adjoining room should be fitted up neatly for the accommodation of the corn-chest, the saddles, and other apparatus; all saddles, bridles, and small articles being properly hung on hooks on the wall, or placed on other appropriate supports. A cupboard for combs, brushes, &c., will be an advantage. If the stable be not supplied with water in pipes, a well should be at hand.

Horses require to be under the charge of persons who understand the business of attending to them in all their varied wants. Some individuals seem to imagine that any boy or lad will do for taking care of a horse. This is both inhumane and bad policy. Where only one horse is kept, a steady lad, under the directions of his master, and instructed in the line of his duty, will often be found sufficient; but he requires constant looking after, for all young persons, and some old ones too, are disposed to play pranks with horses, and rob them of their food. The ordinary class of ostlers are not regularly instructed in the qualities and wants of the horse. All they know is empirical, and their prejudices are frequently absurd. Let all such persons, therefore, be estimated at their proper value; and on committing your horse to any of them at an inn, see that he does his duty to the animal, both as respects cleaning and feeding.

In stables in which two or more horses are kept, a regular groom should be employed; and this person should reside close by the stable, so as to be always at hand. The qualifications of a groom ought to be steadiness of conduct, promptitude in a case of difficulty, openness to advice or instructions, experience in well-managed stables, taste for cleanliness; and he should be as desirous of making his charge comfortable as he would his own person.

If all horses were good-tempered, or rendered docile by kind treatment, they might be advantageously left at liberty in their stalls; circumstances, however, require that they should be restrained; but this should be done with as little pain to them as possible. The halter or rein from the headgear should be led to a ring at the head of the stall, leaving the animal at liberty to lie down in an easy posture. The rein, whether of rope or chain, should not be tied to the ring. It should go through the ring, and drop down with a plummet at the extremity to keep it down, yet allowing the animal to pull it up or allow it to sink at pleasure. A shorter halter may be employed during the day than at night, so as to keep him from straggling backwards into the passage or gangway. Some horses are most restive in restraint, and commit tricks to loosen themselves; and others, by awkwardness of movement, get the halter round their feet, and are thrown down, and occasionally, if assistance be not promptly rendered, are much injured in their struggles to regain their feet. A soft level bed and abundance of room are the best preventives for this kind of accident.

Grooming—Dressing—Trimming.

The skins of horses are liable to become clogged with a scurf of dried perspiration, along with particles of dust and mud, which collect and lodge among the hairs. It is of great importance to remove these impurities by currying and brushing, for the sake of the health of the animal, independently of the value of the operation as respects the appearance of his coat. The degree to which this species of grooming is carried will of course very much depend on circumstances; but, as a general rule, it should take place every morning before the horse is led forth to the labour of the day.

The grooming is commenced while the animal is in his stall—his wrapping-cloth, if he have one, being removed, and the restraining-rein being lengthened, to allow his standing a little back into the gangway. If restive, his head must be tied up. All refuse having been previously removed, a little of his bedding may be drawn out for his hind-feet to stand upon. The first thing done is to curry him with a curry-comb—a flat iron instrument, with rows of short blunted teeth and a handle. By being drawn along the surface of the body and limbs, it rakes up the lumps of hair, and generally loosens and brings up all extraneous substances. The groom commences with the neck and shoulders; next he goes to the body, hinder quarters, belly, and legs, both sides being treated alike. The curry-comb must not in any case be used roughly, and with thin-skinned horses its application must be very gentle. If the horse be regularly groomed, and its work not dirty, a gentle scrubbing with the curry-comb will in most cases suffice. In performing the operation, a brush may be held in the other hand, with which to clear out the teeth when necessary. After the curry-comb has gone its rounds, apply the brush in turn, going over the whole surface with it, from head to heels, to remove all raised impurities, and to lay the coat smooth. A rough hair-glove has been introduced into use as an improvement upon the brush; and it certainly possesses the advantage of being more easily applied to the head, limbs, and flank, than the brush. Should the horse be changing his coat, which he does twice a year, the curry-comb must not be used at all—a rubbing with a straw-wisp being perhaps sufficient.

After the currying and brushing, the groom proceeds to comb the forelock, mane, and tail, so as to make all the hairs lie straight. This finishes the grooming; but if the legs or feet be white, they will perhaps require washing with warm water and soap—to prevent the growth of a yellow appearance—and then dried with a wisp. We have only to add, that if horses are not groomed regularly in this manner, they will inevitably lose their health, or be troubled with parasitical animals lodging beneath the hairs, and never have a glossy and cheerful appearance. Some horses have a great repugnance to being groomed, but this generally arises from harsh treatment while they were young: if treated considerately, they will feel pleased with the friction, and grateful for the attention bestowed on them.

The cleaning of a horse after work is as necessary as the morning grooming. When a horse is brought to the stable in a state of perspiration, it should not be taken in to be at rest all at once, but be walked gently about.

till it becomes moderately cool. This allows the excitement of the blood-vessels and muscles to be allayed gradually, and prevents any sudden stoppage of the pores of the skin. To assist in drying and cooling down the animal, he may be scraped or rubbed with wisps. Wisping is preferable. After the horse has been walked and wisped, his legs and feet should be washed with water and a brush or sponge, and also his belly, if it be dirty with sparks of mud; but, after any such washing, every part should be thoroughly dried with a fresh wisp. Never leave a horse with wet legs or feet. In the country, it is not unusual to walk horses into a river to wash their legs—a practice most detrimental to their health, and which should not be allowed.

When the horse has been cleaned and dried, the cloth may be thrown over him, and he may be tied to his stall. The cloth used in summer should be lighter than that used for winter. It is customary for grooms to exercise horses with the stable-cloths wrapped round them, and then perhaps the next hour they are taken out saddled, and without any cloth at all. This seems an inconsistency. The use of cloths is to protect the animal's loins from cold, and is unnecessary in fine weather. If the horse has to stand still out of doors, and the weather be ungenial, his loins ought by all means to be protected by an oiled cloth. The horse is very susceptible of injury by exposure of the loins; and it will be observed that, to shelter that part, cavalry soldiers wear a long riding-cloak, which falls loosely over the hinder part of the animal.

Nature gives the horse a beautiful flowing tail and mane, for the purpose of whisking off flies, and for other uses; but mankind, in taking the creature under their protection, have in many instances, and for no good reason, as far as we are aware, deprived it of these graceful personal appendages. The most contemptible piece of this rash interference has been the docking of the tail, and causing it to cock up, thus leaving the rear of the animal exposed. The tail should be left flowing to a point, and only trimmed to a limited extent; and the same thing may be said of the mane. Nature has likewise given the animal long hairs on the legs, independently of the fetlocks. These various appendages have likewise not been given unnecessarily; they answer as a kind of thatch to carry off the moisture which trickles down the legs, so as to keep the feet dry and the legs warm. These parts, therefore, should be trimmed sparingly; and the fouler the animal's work, the more should be left on. Any trimming should be executed tastefully with a comb and pair of scissors. It is customary to clip away the long hairs about the ears and muzzle, but this also must be performed with great discretion. These hairs have their uses, those about the ears in particular, and harm is not unfrequently done by their removal.

Management of the Feet.

When the horse has been stabled for the night, it will be the duty of the groom to see that the hoofs, above and below, have been cleaned, particles of sand removed from the crevices of the shoes, and the feet generally in a good condition. The feet have a tendency to harden and crack, and thus a good horse may become lame. The fore-feet are most liable to this serious evil. To prevent hardness and soreness of feet, it is customary to *stop* them at night with a soft moist material—most commonly cow-dung, mixed with oil, lard, or tar. No special directions on this point can be given; for some thin-soled horses do not require stopping, and the hind-feet are seldom in need of anything of the kind. When the frog is liable to thrush, the feet require to be kept dry, and cleaned and attended to with peculiar care. To prevent over-dryness of hoofs, as well as the undue action of moisture, it is advisable to anoint the horny part of the feet with an ointment made of tar, fish-oil, and bees-wax, melted together in equal proportions; but this should not be done unless it is absolutely required. If well washed, and kept clean, the feet will seldom require any of this kind of varnishing.

When at large in a wild state, horses, as may be supposed, go barefooted, like all the other lower animals. The hoofs grow with a slight curve up in front; but this does not seem to impair their speed. If domesticated horses were always to walk on turf, and were not obliged to carry or draw a weight, their feet might remain unshod; but the circumstances of their condition make it necessary to protect the hoofs from tear and wear by means of shoes. Horseshoes have been used of many different shapes and materials; but it is needless here to speak of any others than the iron shoes in common use. The shoe must be of weight conformable to the powers and uses of the animal, made exactly to suit the curve of the hoof, flat, and of equal thickness, and secured by nails to the hoof. The proper paring of the hoof before shoeing, and the shoeing itself, are matters to be left to the discretion of regular farriers. As a general principle, care must be taken not to drive the nails into any tender part, and the hoof should be as little broken as possible. A gentleman's horse should be shod at regular intervals of three or four weeks, and a shoe never suffered to come off from too long usage.

Exercise.

Every horse, when not worked, ought to be exercised daily in the open air. The exercise should be in the early part of the day. An authority already quoted (*Lib. Use. Know.*) observes: 'The horse that, with the usual stable-feeding, stands idle for three or four days, as is the case in many establishments, must suffer. He is disposed to fever, or to grease, or, most of all, to diseases of the foot; and if, after these three or four days of inactivity, he is ridden fast and far, is almost sure to have inflammation of the lungs or of the feet. A gentleman's or tradesman's horse suffers a great deal more from idleness than he does from work. A stable-fed horse should have two hours' exercise every day, if he is to be kept free from disease. Nothing of extraordinary, or even of ordinary labour can be effected on the road or in the field without sufficient and regular exercise. It is this alone which can give energy to the system, or develop the powers of any animal. In training the hunter and the race-horse, regular exercise is the most important of all considerations, however it may be forgotten in the usual management of the stable. The exercised horse will discharge his task, and sometimes a severe one, with ease and pleasure, while the idle and neglected one will be fatigued ere half his labour be accomplished; and if he be pushed a little too far, dangerous inflammation will ensue. How often, nevertheless, does it happen that the horse which has stood inactive in the stable three or four days, is ridden or driven thirty or forty miles in the course of a single day? This rest is often purposely given, to prepare for extra exertion—to lay in a stock of strength for the performance of the task required of him; and then the owner is surprised and dissatisfied if the animal is fairly knocked up, or, possibly, becomes seriously ill. Regular and gradually increasing exercise would have made the same horse appear a treasure to his owner. Exercise should be somewhat proportioned to the age of the horse. A young horse requires more than an old one. Nature has given to young animals of every kind a disposition to activity; but the exercise must not be violent. A great deal depends upon the manner in which it is given. To preserve the temper, and to promote health, it should be moderate, at least at the beginning and the termination. The rapid trot, or even the gallop, may be resorted to in the middle of the exercise, but the horse must be brought in cool. If the owner would seldom intrust his horse to boys, and would insist on the exercise being taken within sight, or in the

neighbourhood of his residence, many an accident and irreparable injury would be avoided. It should be the owner's pleasure, and is his interest, personally to attend to all these things.'

Watering and Feeding.

A horse should be exercised a little after being watered. He should on no account be allowed to drink when heated, particularly if heated to the extent of perspiring. The only refreshment allowed in these circumstances is a rinsing of the mouth, and the muzzle may be washed and relieved of froth. When not permitted to take water of his own accord in the stall, let him be offered a pail three or four times a day; and after drinking copiously at either a pail or pond, he may be trotted or gently cantered, the motion being generative of heat, and at least prevents any chill.

Horses are fed on different materials in different countries; but principally on the various kinds of grasses and cereal grains. The Germans give them feeds of brown bread while on a journey; in India, rice and spices are employed for their diet; in England, the chief articles of food are oats and hay, with inferior proportions of beans, peas, cut straw, and bran. The quantity, and also the nature of the food, will depend on the habits of the animal, and the work to which he is put. If the work be hard, he must be fed to a considerable extent on oats and beans, which are more nutritious than most other articles in use; but if the work be light, a lighter diet of hay, with perhaps only a small quantity of oats, will suffice. The stomach of the horse being small, he cannot eat much at a time; and it is always preferable to feed him often, and at regular intervals, than to offer him large feeds at irregular periods. There is another reason for offering small feeds: the horse nauseates food which he has blown upon, or previously touched, and will accordingly reject it if offered a second time, or allowed to stand beside him. For various reasons, therefore, it is better to give him only a little at a time, so as to leave none behind. If the animal be a poor feeder, or apt to waste his food, greater care must be taken in this respect.

Oats ought to be sound, old, and dry. If musty, reject them. In almost all cases, it is preferable to have them bruised; for by this they are more easily digested and nourishing than if left whole. It is now customary to mix oats with chaff composed of the cuttings of clover or meadow-hay, and the straw of wheat, oats, or barley. In some stables, a machine is kept to cut these materials. The length of the cuttings should be about half an inch. Bruised oats have a tendency to scour the animal; but the admixture of chopped stuff counteracts this quality.

Of hay, clover, and meadow-hay, little need be said. They should be sound and sweet-flavoured, without any mustiness. The hay should, if possible, be a year old, and well saved for use in an adjacent stack. Some horses are fond of peas; but they require to be given with caution, as they are apt to swell in the stomach. Almost all horses are inordinately fond of carrots, which, when administered in small quantities, do not purge the animal, and improve his coat. A respectable authority states, that 'for agricultural and cart horses, eight pounds of oats and two of beans should be added to every twenty pounds of chaff; and thirty-four or thirty-six pounds of the mixture will be sufficient for any moderate-sized horse [daily] with fair or even hard work.' In this estimate, no hay is supposed to be given. When the horse is fed on the last two articles, hay and oats, four feeds, or nine or ten pounds of oats per day, will be a fair allowance during winter, and in the case of moderate work; but in summer, half the quantity, along with a proportion of green herbage, will suffice. Many gentlemen follow a general rule of allowing twelve pounds of oats per day to each riding-horse, and this is given in three or four meals. A pony, having but moderate work, will be well fed on six pounds of oats per day with a fair proportion of hay. Latterly, sago has come into use as an article of horse-diet; and we believe it is tolerably nutritive, and may be employed to a certain extent to supersede oats, or to be mixed with them. It should be partially softened by preparation.

THE DISEASES OF HORSES.

In consequence of the general mismanagement and ill-treatment of horses, they are exposed to a number of formidable diseases. Those of most frequent occurrence are inflammation of the lungs, broken-wind, inflammation of the bowels, and certain illnesses of the feet and legs. Referring our readers to larger works on the horse for full information on these diseases, and recommending all unskilled persons at once to hand over their horse to a veterinary surgeon when unwell, we propose only to give a few hints as to the best means of prevention. The institution of schools of veterinary surgery, at which the anatomy, peculiar nature, and diseases of horses are explained by men skilled in this important department of science, has been a powerful auxiliary in improving the qualities of horses, preserving their lives, and saving them from much needless distress.

Inflammation.

The more ordinary inflammation is that of the lungs, and is caused by sudden changes of temperature; it is, in reality, the grand disorder of the horse, and its effects are only paralleled by those of pulmonary consumption in the human species. Already we have spoken of the great impropriety of exposing horses, while heated, to cold draughts. Allowing them to stand any length of time in the open air, in cold or moist weather, is equally objectionable, and positively cruel. Inflammation of the lungs, however, will arise from various causes besides cold, and these have engaged the most serious attention of veterinarians.

In a prize-essay awarded several years ago by the Highland Society to Mr M. Milburn, Yorkshire, the essayist observes: 'The post-horse, and such as are required to perform fast work, are more liable than heavier draught-horses to diseases of the brain, the nerves, and the lungs, simply because their work consists of rapid and powerful exertion; the farm-horse, the animal of long and steady exertion, to gripes, inflammation of the bowels, and stomach-staggers—results, as I shall presently shew, of a management unsuited to the character of the labour we require from them. The stomach of the horse is remarkably small—smaller in proportion to his size, and the quantity of food he requires, than any other domestic animal. Nature intends for him a supply of nutritious food, and that *at short intervals;* wherein he materially differs from the ox, whose capacious stomach will contain food which will not be digested for hours. The post-horse, the hunter, and the carriage-horse, have food of the most nutritious description, and the time during which they are worked is necessarily short, owing to the extreme exertion required; they return to their food; and although their appetite may for a time be impaired, and their stomach and bowels affected by the general debility of the system, yet they recover their tone as soon as the rest of the frame admits of their taking food. The farmer's horse, on the contrary, has food of a less nourishing nature; his rack is filled with straw, or at best with clover; the ploughman rises early, gives him a feed of corn, and leads him to his work, where he continues for seven, eight, and even nine hours, and his whole day's work is completed before he is allowed to eat. We do not find the ox, worked under similar circumstances, so affected in the stomach and bowels, simply because his capacious stomach, when filled, requires many hours to empty; while, as we have seen, it is different with the horse. Debilitated and hungry, the horse returns, and his rack

is plentifully supplied, and a good feed of corn given him, and he is left to himself: he eats voraciously, half masticates his food, loads his debilitated stomach, and his digestive organs are weakened, and permanently injured. This course is repeated—a habit of voracity is acquired; and at no very remote period the food lodges and obstructs the pyloric orifice—the passage from the stomach to the bowels—fermentation ensues, gas is evolved, the stomach is distended, he grows sluggish and sleepy, drops his head upon his manger; or he is delirious, and evinces that the sympathy which exists between the stomach and the brain has excited the latter organ; he rolls, paws, and is seized with convulsions; at length he expires, and he has died of stomach-staggers. The half-masticated food has irritated the bowels, extra exertion of the muscles has been required to propel the fæces to the rectum, and colic or cramp (spasms) of the bowels has followed; or a course of continued irritation, or of continued colic, or both, has ended in inflammation of the bowels. I remember a beautiful farm-horse, which, owing to the distance of part of the farm to which he belonged from the buildings, was worked the long hours described, and finished his day's work before his bait. He was constantly subject to attacks of the gripes, which were subdued; but he died of stomach-staggers. The same stable, then so often subject to diseases, is now, by a change in the system, completely free from them. Another case, however, occurred: a beautiful compact little mare was constantly afflicted by colic; she eventually died of inflammation of the intestines.

'There are other parts of the management to which horses employed in agriculture are subject, which induce diseases of the bowels. For instance, a boy returning from work, with heated and sweating horses, to save himself trouble, allows them to drink copiously at some pool or stream he passes. Suddenly one or more of the horses exhibit symptoms of gripes; they suddenly lie down, roll about, look at their sides, rise up, seem relieved, and again speedily relapse; the sudden application of the cold water has produced spasms in the bowels, through which it has passed. This is neglected, or perhaps gin or whisky, aided by pepper, is administered as a remedy, and severe and general inflammation of the bowels is the result: this is mistaken for another attack, and again the poison is administered, and the inflammation increased, and death follows. The horse of heavy work, too, is longer exposed to the inclemencies of the weather than the animal of light work. In the former, the rain is allowed to fall upon him for hours, and then *to dry upon his back:* the sympathy between the skin and the alimentary organs is known to every groom; obstructed perspiration, and consequent irritability, is conveyed from the one to the other, and disease is the consequence. It is true the latter is also partly exposed to the rain, but for shorter periods, and the wisp and brush are liberally applied when he enters the stable; a determination of blood takes place to the skin, perspiration is promoted, and disease thus prevented.

'Of the best means of preventing these diseases in farm-horses we will now treat: we have attributed the peculiar liability to them in farm-horses to mismanagement, with the exception of certain instances of peculiar formation of the animals; and although the farmer must necessarily work his horses longer hours than the horse of rapid work is capable, there is no necessity for depriving the animal so long of food. No horse should work more than five or six hours without a bait. If we examine the history of the stables of large farmers, whose fields necessarily lie at a great distance from the buildings, and where they are worked long in consequence, and compare it with that of small farmers under the contrary circumstances, we shall find a striking difference as respects the health of the animals. The case referred to above strikingly illustrates the truth of this observation. But it may be asked—How is it possible to bait the animals so far from home? The difficulty seems to be in procuring food upon the spot; for if this is not done, the precaution will be neglected, and at anyrate the land will be occupied by it. This, however, may be remedied. In the case, for instance, of a field intended for turnips, which has to be worked during the spring, a part of it, half an acre, or in proportion to the size of the field, may be sown with winter-tares, a few of which may be mown off, and given to the animals green, without carrying them from the field, interfering with any crop, or wasting any time in carrying the horses to a distance. If the field be intended for summer-fallow, the spring tare will answer, and which may be used in the same manner, instead of allowing the poor animals greedily and indiscriminately to crop the leaves of the hedges at every turning, from the impulse of hunger. There is another easy way of baiting, which some carters adopt, and which might be applied to the farmer's horse, especially when carting. It consists in securing a bag containing corn over the animal's mouth and nose, by a string, which passes over the poll, and is locally denominated a "nose-bag," or "horse-poke," and which should be removed when he has finished his feed. To prevent the effects of the wet upon the skin, an unexpensive glazed cloth may be thrown over the horse's back, and secured to the collar and traces. This may by some be considered very troublesome; but it will be found that when it is once begun, it will be considered no more trouble than carrying the rest of the harness; and if disease is prevented, the trouble amounts to nothing. To counteract as much as possible any habits of greedy feeding which the horse may have acquired, his corn should be mixed with chopped straw, or chopped clover, which will secure its proper mastication, and prevent many troublesome complaints, as well as render all the nutrition of the food available. These may be substituted by an admixture of clean chaff with corn—a plan which is pursued in a farm-stable with which I am acquainted, and is found a useful practice. It would save the animals much time in eating if all their food was chopped, and perhaps steamed; but on this subject we have not sufficient data to determine with accuracy.'

The cure, it has been hinted, must generally be left to the veterinary practitioner, whose chief object should be to empty the stomach. In severe cases, an ounce of laudanum and a drachm of pounded ginger, in a quart of warm ale, may be used with probable success.

Broken-wind.

When the breathing of a horse is rapid and laborious, it is said to be *thick-winded;* and when it breathes irregularly, the inspiration taking one effort, and the expiration two, it is called *broken-wind.* Inflammation of the lungs from cold is a cause of thick-wind, the condition of these organs preventing the full action of the air-tubes. The chief cause of broken-wind is sharp work after over-feeding—causing the animal to run while the stomach is full. Grossly fed, badly managed horses, are hence most subject to the complaint. Carriage and coach horses are seldom broken-winded, unless they bring the disease to their work, for they live principally on corn, and their work is regular, and care is taken that they shall not be fed immediately before their work. The farmer's horse is the broken-winded horse, because the food on which he is fed is bulky, and too often selected on account of its cheapness; because there is little regularity in the management of most of the farmer's stables, or the work of his teams; and because, after many an hour's fasting, the horses are often suffered to gorge themselves with this bulky food; and then, with the stomach pressing upon the lungs, and almost impeding ordinary respiration, they are put again to work, and sometimes to that which requires considerable exertion. The agriculturist knows that many a horse becomes

broken-winded in the straw-yard. There is little nutriment in the provender which he there finds; and to obtain enough for the support of life, he is compelled to keep the stomach constantly full, and pressing upon the lungs. Some animals have come up from grass broken-winded that went out perfectly sound. The exact nature of the disease is unknown. It appears, however, to consist in a paralysed condition of the bronchial tubes and remoter air-cells, which renders expiration more difficult, and necessitates the double effort so characteristic of the malady.

'The cure of a broken-winded horse no one ever witnessed; yet much may be done in the way of palliation. The food of the animal should consist of much nutriment condensed into a small compass; the quantity of oats should be increased, and that of hay proportionably diminished, the moistening of the hay is also usually beneficial; the bowels should be gently relaxed by the frequent use of mashes; water should be given sparingly through the day, although at night the thirst of the animal should be fully satisfied; and exercise should never be taken when the stomach is full.' Under such management, and at slow work, a broken-winded horse will often remain serviceable for years.

Curb—Bog-spavin—Bone-spavin.

The hock-joint is particularly liable to derangement, so as to render the animal unsound. One of these affections is called *curb*, which arises from overexertion of the ligaments, and takes the form of an enlargement a few inches beneath the joint of the hock. A more serious complaint of the hock is the *bog-spavin*, which takes place from overexertion, and is an inflammation in the vesicles containing the lubricating material for the joint. This disease is almost incurable; and the poor animal is in general only fit for ordinary and moderate work all the rest of his life. The *bone-spavin* is a still more formidable disease. It is an affection of the bones of the hock-joint, caused by violent action, or any kind of shoeing which throws an undue strain on certain ligaments, and deranges the action of the bones. A bony deposit takes place, the joint is stiffened, and the consequence is a lameness or stiff motion in the hind-legs. Blistering as a counter-irritant, and rest, are the principal remedies prescribed for this complaint; but the best thing of all, so as to *prevent* not only this, but all other similar complaints, is never to overload the horse, or put him, especially before he comes to his full strength, to any violent exertion.

Physicking.

Horses even when attended to with the greatest care, occasionally get into a condition which requires physic—that is, purgative medicine; as, for example, when they have been too long on hard food, and require a laxative; when they get into a heated state of body from constant high-feeding; when their bowels get overloaded or disordered; or when they are getting too fat. The most simple laxative is a *bran-mash*. Bran is put into a pail, and softened with boiling water; when cooled sufficiently, it is given to the animal as the last feed at night, instead of corn or hay. About half a pailful is a dose. Horses used by commercial travellers or others during the whole week, and fed on corn, are indulged in a mash on Saturday night; and this, with the rest on Sunday, keeps them in good condition. When a working-horse is lamed, or becomes sick, and must remain idle for a few days, he requires to be relieved by a dose of physic. Generally, this consists of from four to seven drachms of Barbadoes aloes, powdered, and formed into a round moistened mass, fit to be swallowed. It requires to be administered by a skilful groom, who will push it over the throat adroitly, without alarming the animal. Sometimes the powder is mixed with a little Castile soap. An hour or less after taking physic, a bran-mash should be given, and then the horse be gently exercised. On his return to the stable, he may be offered a drink of water from which the chill is taken, or as warm as he will take it.

We should consider it imprudent to offer any further explanations of the materia medica of horses; and again recommend all unskilled or but partially instructed persons not to attempt doctoring their horses themselves, but to obtain at once the advice of a veterinary surgeon.

ADVICE IN PURCHASING A HORSE.

The purchasing of a horse is ordinarily a matter of very serious difficulty, in consequence of the proverbial trickiness of dealers, and the many defective points in the animal's constitution, which cannot be seen with all the care that may be bestowed. In offering any hints on this important particular, we must refer to the instructions of authorities whose testimony is worthy of confidence. Mr Stewart has written a valuable little manual, entitled *Advice to the Purchasers of Horses*, which should be in the hands of all who have frequent occasion to make purchases. The following are a few of his admonitions:

'In buying a horse, one of the chief requisites to be attended to is the degree of nervous energy which the animal possesses; and it is the union of this energy with good conformation that makes many horses invaluable. Its absence or presence, however, is not likely to be discovered by the purchaser without a trial; and to avoid disappointment in this respect, it is therefore advisable to obtain one prior to purchase. The horse should be set to the work he will be called on to perform; and if he is intended for the saddle or single harness, he should have no companion on his trial, for many animals work well in company that are downright sluggards when alone. Some horses have an unpleasant way of going, or are difficult to manage, or have some vice which is only displayed when at work: these are so many more reasons for having a trial prior to striking a bargain. But if that cannot be obtained, some sort of conclusion regarding the animal's spirit may be drawn from his general appearance. The way he carries his head, his attention to surrounding objects, his gait, and the lively motion of his ears, may all or each be looked to as indicative of "bottom," or willingness to work. It is only, however, in a private stable, or in that of a respectable dealer, that these *criteria* can be depended upon; for in a market-place, the animal is too much excited by the cracking of whips, and the too frequent application of them, to be judged of as regards his temper. Neither must the buyer be thrown off his guard by the animation which horses display at an auction, or on coming out of the stable of a petty dealer; for it is a fact, which cannot be too well made known, that there are many unprincipled dealers who make it their business, before shewing a horse, "to put some life in him"—that is, they torture him with the lash, till, between pain and fear, the poor animal is so much excited, as to bound from side to side with his utmost agility at the least sound or movement of the bystanders.'

This writer continues, in relation to the head and other parts of the animal: 'The head, as being a part not at all contributing to progression, should in the saddle-horse be small, that it may be light; the nostrils expanded, to admit plenty of air, and the space between the branches of the lower jaw, called the channel, should be wide, that there may be plenty of room for the head of the windpipe. In the draught-horse, a heavy head is not, so far as utility is concerned, an objection, for it enables him to throw some weight into the collar; and hence, excepting its ugliness, it is rather an advantage, if he is used entirely for draught. But it makes the saddle-horse bear heavy on the hand of the rider, makes him liable to stumble, and, when placed at the end of

a long neck, is apt to wear out the fore-feet and legs by its great weight. The neck of the saddle-horse should be thin, not too much arched, and rather short than long, for the same reason that the head should be light; and in the draught-horse it may be thick, stallion-like, and sufficiently long to afford plenty of room for the collar, and for the same reason that the head may be large in this animal. The windpipe should be large, and standing well out from the neck, that the air may have an easy passage to and from the lungs. A horse intended to be used for the miscellaneous purposes of carriage and draught, should have a head and neck neither too light nor too heavy.

'That the saddle-horse may be safe, and have extensive action, it is necessary that the withers be high. This advantage is indicated by the horse standing well up before; and it is usual, in shewing a horse, to exaggerate the height of the forehand by making him stand with his fore-feet on a somewhat elevated spot. A horse with low withers appears thick and cloddy about the shoulder. In the ass and mule, the withers are very low, and the shoulders very flat, and this is the reason why they are so unpleasant to ride, and why it is next to impossible to keep the saddle in its proper place without the aid of a crupper. High withers, however, are not essential to the racer or the draught-horse. The former does all his work by leaps, and that is performed best when the horse stands somewhat higher behind than before: neither are high withers necessary to the draught-horse; but in the roadster, they are as important as the safety of the rider is, for a horse with a low forehand is easily thrown on his knees. In the draught-horse, this tendency towards the ground is obviated by the support the collar affords.

'The chest should be deep and wide in all horses, but especially so in one intended for quick work, in order that there may be plenty of room for the play of those important organs, the lungs.

'The back should not be too long nor too short; for though length is favourable to an extended stride and rapid motion, yet it makes the horse weak, and unable either to draw or carry any considerable weight. On the other hand, if the back be too short, the horse's action must be confined; and short-backed horses, in general, make an unpleasant noise when trotting, by striking the shoe of the hind-foot against the shoe of the fore one; and though they are in general very hardy, and capable of enduring much fatigue, and of living on but little food, yet a back of middling length is better by far than one immoderately short or long. The back should be nearly straight.

'In the saddle-horse, and where safety is desirable, the position of the fore-leg is worthy of attention. It should be placed well forward, and descend perpendicularly to the ground, the toe being nearly in a line with the point of the shoulder. The pasterns should neither be turned in nor out. When they are turned inwards, the horse is in general very liable to cut the fetlock-joint by striking the opposite foot against it. The draught-horse may be excused though he leans a little over his fore-legs, but the saddle-horse will be apt to stumble if he does so.'

Minute attention should be bestowed on the examination of the fore-legs and feet; these, in fact, are the great trying-points. If the feet be not round and full, so as to stand firmly and flatly on the ground, and if tender or thin in the hoofs, the animal is not to be trusted for saddle-work. Mr Lawrence on this subject remarks: 'The feet of saddle-horses, be they ever so sound and good in nature, detract greatly from the value of the nag, unless they stand even on the ground; since, if they deviate inward or outward, the horse will either knock or cut in the speed—that is to say, will strike and wound the opposite pasterns either with his toe or his heel; and if he bend his knees much, and is a high goer, will cut the inside of the knee-joint. Nature has been very favourable in the hinder hoofs, with which we have seldom much trouble; but there is, now and then, a most perilous defect in them—namely, when the horse is so formed in his hinder quarters that he overreaches, and wounds his fore-heels with the toes of his hind-feet.' The defect here spoken of will be observed to cause an unpleasant clattering noise in trotting. The fore-legs, from the knees downwards, should be clean made, sound, and flexible at the joints. Bad usage knocks up a horse, or founders him; and his legs, being in a kind of benumbed state, will either wholly or partially refuse to perform their office. By ease and physicking, the horse recovers; but his system has been shaken, and he is apt to come down. This is a fearful defect in a horse; for no one is for a moment safe on his back. Weakness in the fetlock-joint will also cause a horse to stumble and come down, and is therefore an equally serious defect. When the horse stumbles either through weakness or bad management, so as to come down on his knees, the likelihood is, that the knees are broken; and it is well known that wounds of this nature never heal over to resemble the original. The horse with broken knees is, in short, damaged for life, at least in as far as he is a marketable commodity.

Horses are sold either with or without warranty. At sales at repositories, the terms of warranty are generally announced in a public manner; but when the sale is private, no warranty is binding which is not expressed in writing in the receipt. The principle that a price above £10 warrants a horse sound, is not now recognised as binding. The warranty, to be of any legal value, must be something different from a mere verbal understanding or illusory custom.

DUTY OF HORSES.

Draught.

The horse is equally willing to make himself useful as a beast of burden or draught; but his powers are best adapted for the latter, and particularly on a level road. The formation of his body does not suit him for climbing or going uphill with a load; and his strength is always exerted to greatest advantage when he can throw his centre of gravity forward as a make-weight. The amount of load which he can draw in a wheeled vehicle depends on the arrangement of the load to the pull. The pulling-point is across the shoulders, and the most advantageous method is, to make the line of traction proceed *direct* from the shoulders to the load—in no shape bent or distracted from its course. The load should be placed lower than the line of the shoulders, thus making the line of traction go by a straight slope to the seat of resistance. The load should not be at a greater distance than will allow freedom of motion to the hind-legs. If it be placed too low, a part of the power will be uselessly spent in upholding it.

According to the calculations of James Watt, the weight which a horse can draw, called a *horse-power*, is 1,980,000 pounds raised one foot high per hour, or 33,000 pounds raised one foot per minute. The weight is supposed to hang at the end of a rope passing over a freely-moving pulley. This calculation is based on considerations more favourable than those which usually attend horse-labour. There are, in reality, no rules to guide the imposing of loads on horses; for everything depends on the degree of friction on the wheels of the carriage, the nature of the road, and the strength of the animal in question. One thing is certain, that a horse always exerts his power better by himself than when yoked with others. The load which it requires four horses to draw unitedly, if divided, could be drawn with equal ease by three. The following observations, referring to the operations of Sir C. Stuart Menteith, deserve to be noticed:

'From the experience this gentleman has had in the

use of animal power upon common roads, he is of opinion that the most economical mode of employing horses in draught is to give every horse his own carriage, and that he should solely depend upon his own exertions in drawing the load, as otherwise it is well known that it is difficult to find either man or beast equally willing or capable to make the same exertion, or to have the same spirit or motion; and at the same time never to exceed six miles on one stage, and to be performed twice daily. In a stage of three and a half miles, Sir C. S. Menteith employs wagons weighing eighteen hundredweights, in which horses draw three tons. The road is in general upon a declivity of one foot of fall for every eight, sixteen, or eighteen feet, with several ascents of one foot in every thirty feet, up which a horse draws the load of three tons, and a wagon of eighteen hundredweights; but in order to facilitate the ascent, a continuous line of sandstone railroad is first laid down, upon which a plate of iron, six inches wide by a quarter of an inch thick, is fixed down. In order to enable a horse to bring a load of three tons down any rate of descent, a friction-break has been employed, similar to the one in common use in Belgium, from which Sir C. Stuart Menteith derived this important application. The break is a strong plank fixed to the back of a cart or wagon, which, by means of a screw, the carter presses against the two hind-wheels of the machine, so as to give a sufficiency of friction to retard the too rapid descent of the carriage. If the employment of horse-wagons, weighing from twelve to thirteen hundredweights, were adopted in conveying coal through the streets of London, one horse would do the work of two: at present, four immense horses draw three chaldrons of coal, or four tons one hundredweight, in a wagon weighing perhaps two tons; so that the shaft-horse is obliged to draw a weight of six tons in turning out of one street into another.'

The larger the size of wheels in a vehicle, within a reasonable proportion, so is the friction in overcoming obstacles on the road less, and so is the draught more easy to the horses. The benefits of large wheels, however, have often been completely lost by not making them run fairly in an upright position. The custom has been to make them *dished* or bevelled outward from the axle, and to cause the axle to lean downward at each extremity to accommodate this peculiar shape. It is of importance to understand that a wheel always runs best when its tire is of equal diameter, when the spokes are at right angles to the axle, and when the axle projects straight out. This is exemplified in the trundling of a hoop: a hoop which is perfectly upright and even on the rim, requires less force to send it forward and keep it moving than if it were bevelled, and inclined to go round in a circle. For the sake of convenience, wheels may be a little dished, though now, that the roads are good, that is scarcely necessary.

The power of draught of a horse depends on the rate at which he is compelled to proceed. He exerts his power to most advantage at a fair pull, when moving at the rate of from two and a half to three miles per hour. If he go at a greater speed, he is less able to draw. As a general rule, if the speed be doubled, the load should be halved; and if the speed be twice doubled, the load should be quartered; yet this will only hold as correct for short distances. Much work may be procured from a horse if he be impelled only for short stages. A horse in a stage-coach, running only five miles at a time, and then resting for a few hours, will last at least four times longer than another horse of equal power which runs ten miles at a time. This is well understood by all stage-coach proprietors, and short stages have now almost everywhere superseded long ones. Such a fact should also be known to all private travellers. Whether employed in a gig, chaise, or for riding, the horse on a journey should take his day's work in two distinct stages—one in the morning, and another in the afternoon, when rested and refreshed. He should also, to remain in good condition, have a rest during the whole of Sunday. In journeying with light loads, a distance of from twenty to twenty-five miles is considered a sufficient day's task.

Riding.

The art of riding or equitation forms a regular branch of instruction, and is seldom well performed by those who have not been regularly taught. It is not to be supposed that anything we can say can supersede the instructions of the riding-school; but it may be of use to offer a few hints on the subject from the most esteemed authorities.

Riding should be performed in that manner which is least calculated to oppress the horse and fatigue the rider, and which will be most secure for both parties. The first principle in horsemanship is, that the horse and his rider should act and react on each other as if governed by one common feeling. To attain this end, the rider must acquire the knack of balancing himself properly on the animal, and establishing the means of making himself understood through certain movements of hand and body. A good horseman will act according to the following directions, given in Walker's *Manly Exercises*: 'The place of the rider's seat is that part of the saddle into which the rider's body would naturally slide were he to ride without stirrups. This seat is to be preserved only by a proper balance of the body, and its adaptation to even the most violent counteractions of the horse. In relation to the thighs, the rider, sitting in the middle of the saddle, must rest chiefly upon their division, vulgarly called the fork, and very slightly upon the hips. The thighs, turned inward, must rest flat upon the sides of the saddle, without grasping; for the rider's weight gives sufficient hold, and the pressure of the thighs on the saddle would only lift him above it. The knees must be stretched down and kept back, so as to place the thighs several degrees short of a perpendicular; but no gripe must be made with them, unless there be danger of losing all other hold. If the thighs are upon their inner or flat side in the saddle, both the legs and the feet will be turned as they ought to be. Thus turned, they must be on a line parallel to that of the rider's body, and hang near the horse's sides, but must not touch; yet they may give an additional hold to the seat, when necessary, and the calves must act in support of the aids of the hands. The heels are to be sunk, and the toes to be raised, and as near the horse as the heels, which prevents the heel touching the horse. As to the body, the head must be firm, yet free; the shoulders thrown back and kept square, so that no pull of the bridle may bring them forward. The chest must be advanced, and the small of the back bent a little forward. The upper parts of the arms must hang perpendicularly from the shoulders, the lower parts at right angles with the upper, so as to form a horizontal line from the elbow to the little finger. The elbows must be lightly closed to the hips, and, without stiffness, kept steady, or they destroy the hand. The wrist must be rounded a little outwards. The hands should be about three inches from the body, and from the pommel of the saddle, and from four to six inches apart; the thumbs and knuckles pointing towards each other, and the finger-nails towards the body. When the rider is in the proper position on horseback without stirrups, his nose, breast, knee, and instep are nearly in a line; and with stirrups, his nose, breast, knee, and toe are in a line. The man and the horse throughout are to be of a piece. When the horse is at liberty, or disunited as it is termed, the rider sits at his ease; and as he collects and unites his horse, so he collects and unites himself. There must, however, be no stiffness of manner more than in sitting on a chair; for it is ease and elegance which distinguish the gentleman.'

Riding, to one accustomed to it, is best performed

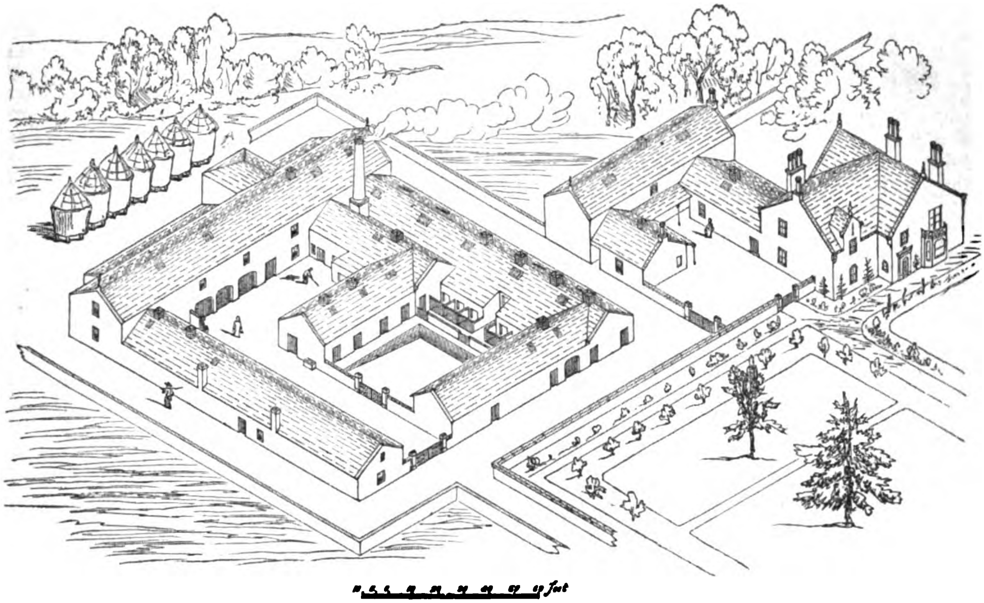
with a curb and snaffle bridle; the curb, however, being only employed to bring the animal up by pressure on the mouth when occasion requires. As some horses have a much more delicate mouth than others, the nature of the bridle must depend on circumstances. In holding the reins, a union of firmness, gentleness, and lightness is the essential requisite. The foregoing authority alludes to the manner in which the reins are to operate on the mouth of the animal: 'The hand being connected with the reins, the reins to the bit, the bit operating in the curb on the bars, and in the snaffle on the lips, the rider cannot move the hand, and scarcely even a finger, without the horse's mouth being more or less affected. This is called the *correspondence*. If, moreover, the hand be held steady, as the horse advances in the trot, the fingers will feel, by the contraction of the reins, a slight tug, occasioned by the cadence of every step; and this tug, by means of the correspondence, is reciprocally felt in the horse's mouth. This is called the *appui*. While this relation is preserved between the hand and mouth, the horse is in perfect obedience to the rider, and the hand directs him, in any position or action, with such ease, that the horse seems to work by the will of the rider rather than by the power of his hand. This is called the *support*. Now, the correspondence, or effective communication between the hand and mouth—the appui, or strength of the operation in the mouth—the support, or aid, the hand gives in the position or action, are always maintained in the *manège* and all united paces. Without these, a horse is under no immediate control, as in the extended gallop or at full speed, where it may require a hundred yards to pull before we can stop him. The degree of correspondence, appui, and support, depends, in horses otherwise similar, on the relative situation of the hand. The act of raising the rider's hand increases his power; and this—raising the horse's head—diminishes his power. Depressing the rider's hand, on the contrary, diminishes his power; and this—depressing the horse's head—increases his power.'

Much may be done to animate a horse, either in riding or drawing, by addressing a cheerful word to him, instead of the lashing and scolding with which he is too frequently visited. If a horse requires correction or urging by the whip, he should only be touched lightly behind the girth and saddle, never on any account on the head or on a fore part of the body. We have frequently seen riders so lost to humanity as to whip their horses when restive over the head and ears. Should a horse attempt to baffle his rider, he must be pressed by the legs, urged lightly with the spur, and kept in his proper track, but not drawn up with the curb or terrified by abuse.

The most common pace in road-riding is the trot, which, in effect, is a rapid walk, and most difficult for a rider to perform with address and a small degree of fatigue to himself. In slow trotting, the body should adhere to the saddle, and when it becomes fast or rough, the body may be raised at the proper moments to ease the jolting. This rising of the body, however, is to be a result of the horse's action, not an effort of the rider. The proper method is to rise and fall with the leading foot, the body rising from the seat when the foot is elevated, and falling when it sinks.

In the course of either slow or fast riding, the horse may trouble his rider by plunging, shying, or restiveness. If he kick and plunge, sit upright, hold on by the legs, and do not vex him by any lashing; when let alone, he is not long in coming out of his freak. When he shies, or flies to one side, as if afraid of something, press him on the side to which he is flying, keep up his head, and bring him into his track. Pressing both legs against his sides will generally keep him from running backward. When he becomes restive—that is, turns round, and has a disinclination to go in the way he is required, the rider must keep him in his track by dint of pressure, a touch of the spur, and the hand. If he has been accustomed to spurs, and finds that your heels are not provided with these appendages, your case is very hopeless. We must allow Walker to point out the course to be pursued with a restive horse. If he persists in turning round, the rider must continue 'to attack his unguarded side, turn him two or three times, and let the heel and spur, if necessary, assist the hand, before he can arm or defend himself against it. If he still refuse to go the right way, the rider must take care that he go no other, and immediately change his attack, turning him about and reining him backward, which the horse is easily compelled to do when he sets himself against going forward. In these contests, the rider must be collected, and have an eye to the surrounding objects; for restive horses try their utmost to place their riders in awkward situations, by sidling to other horses, carriages, the foot-pavement, the houses, &c. In this case, the rider, instead of pulling him from the wall, must bend his head to it, by which his side next the wall is rendered concave, and his utmost endeavours to do injury are prevented. The instant, therefore, that the rider perceives his horse sidling to any object, he must turn his head to that object, and back him from it. There are some horses who fix themselves like stocks, setting all endeavours to move them at defiance. There, happily, their defence can in no way endanger the rider. It must, however, be converted to punishment. Let them stand, make no attempt to move them, and in a short space—frequently less than a minute—they will move of themselves.' The same author recommends the rider to remain perfectly cool in all these awkward circumstances. 'When passion,' he observes, 'possesses the rider, it prevents that concord and unity taking place which ever should subsist between the rider and his horse. He should always be disposed to amity, and never suffer the most obstinate resistance of the horse to put him out of temper.'

Neither in the above section nor elsewhere have we said anything of the accoutrements of the horse, as every article of this kind must be left to the taste of the party concerned. The harness made by all saddlers is now handsome, convenient, and durable, and so well calculated for the comfort of the wearers, that it would be superfluous to say anything respecting it, further than to recommend that it be always kept clean and glossy, and that it do not gall or press unduly on any part of the animal's body.



Open-courted Steading for Dairy-farm of 250 acres.

CATTLE—DAIRY HUSBANDRY.

NEXT to the horse, the cow is justly valued as the most useful animal that man has been able to domesticate and retain permanently in his service. The ox tribe, of which it is the female, belongs to the order *Ruminantia*, in the class *Mammalia*—these terms implying that the animals ruminate or chew their food a second time, and have mammæ, or teats, with which they suckle their young. In the ox tribe (*Bovidæ*), there are different species, all more or less varying from each other. Of the domesticated ox (*Bos Taurus*), the varieties, from the effect of climate, with attention to selection and care in feeding, are now very numerous. The ox, in one or other of its varieties, has been domesticated and carefully reared from the earliest times, for the sake of its labour as a beast of draught, for its flesh, or for the milk of its female. In some parts of Asia, the ox is used for riding and for carrying burdens, similar to the camel in the East, or the packhorse in Europe. In ancient Egypt the ox was raised to the rank of a divinity; while in India, at the present time, he is by several of the Hindoo castes, held as an object of extreme veneration.

The domesticated species of the family, common to the British Isles and Europe generally, is, in all its varieties, materially altered from its wild parentage. Influenced by climate, peculiar feeding, and selection in the domesticated state, its bony structure is diminished in bulk, its ferocity tamed, and its tractability greatly improved. The ox in a wild state is kept at Hamilton Palace, and also at Chillingham Park, Northumberland. Our observations in the present sheet will refer chiefly to the domesticated ox, on which very great changes have been effected by domestication. The most remarkable of these is an increased capacity in the female for giving milk. In a wild state, the udder is small; but when domesticated for the sake of its milk, and the lactic fluid is drawn copiously from it by artificial means, the lacteal or milk-secreting vessels enlarge, and the udder expands, so as to become a prominent feature in the animal. In this manner, by constant attention, the economy of the cultivated species has been permanently altered, and rendered suitable to the demands which are made on the cow. Yet it is important to remark, that those milk-yielding powers are not equal in the different varieties or breeds. Some breeds, from the influence of circumstances which it is here unnecessary to inquire into, give a large quantity of milk; while others yield less, but of rich quality. The quantity and quality of the milk depend, however, on various conditions. The principal are, the age of the animal, the feeding, the housing, &c. In the more highly cultivated breeds, the variations in the flow and in the quality of the lactic fluid in different animals are often remarkable. The cause or causes are usually extremely difficult to account for. In general, near large towns, where the demand for milk is considerable, the object of dairymen is to keep cows which will give a large quantity of milk.

VARIETIES OR BREEDS.

The breeds of cattle throughout the United Kingdom vary in different districts, from the small hardy varieties of the Shetland and Orkney Isles, and the north and west Highlands, to the handsome and more bulky breeds of the arable districts.

Short-horn.

The *Short-horn* or *Teeswater* breed is considered of great value, both for milking and feeding. The best strains of blood are large in the carcass, well proportioned,

broad across the loins, chine full, legs short, head small and handsome, neck deep, in keeping with the size of the body, skin thin and mellow, colour generally white or red, or red and white mixed, or roan. The flesh of the Short-horn is thick and close-grained, the lean and fat well intermixed, and retains the juices. From this circumstance, it is in request for victualling ships going on long voyages.

Authorities are at variance with reference to the milking qualities of this breed; some asserting that, unless the climate and food are very favourable, they are seldom good milkers, having a greater tendency to produce fat than milk; others, again, maintaining that any deficiency in their milking capabilities arises not from the peculiarities of the breed, but from the neglect of breeders to develop the property of giving milk, their attention being chiefly bestowed on the development of flesh and fat. The dairies in London and the neighbourhood of the metropolis are generally occupied with cows of this breed, or of crosses of the Short-horn. As grazing-cattle, they stand first in point of value. Their 'aptitude to fatten,' says a writer in the *Cyclopædia of Agriculture*, 'and the amazing weight and maturity of carcass to which they attain while their age is only reckoned by months; their symmetrical form, rich colour, and quiet temper,' have 'secured to them the pre-eminence over all other cattle. So thoroughly, indeed, do they meet the requirements of our arable husbandry in its highest modes, that we may warrantably expect, at no distant day, to find them recognised as *the one appropriate breed* of the lowlands of the kingdom.' Animals of this breed generally realise high prices. At recent sales of herds of short-horns, the average prices of the whole—bulls, cows, heifers, and calves—ranged from £50 to upwards of £90. Occasionally, animals have been sold at sums almost fabulous; three having been bought in England at £1000 each, for Mr Thorne, state of New York, United States. A bull, three years old, named Master Butterfly, was purchased for Australia in 1856 for the sum of £1250. The demand for Short-horns is yearly increasing, and consequently higher prices are obtained for the best specimens of the breed.

The *Herefords* are to be found in perfection in the county from which the name is derived. They are of large size, with round cylindrical forms; the back and quarters broad; the head of moderate size; muzzle, broad; eye, large, prominent, and placid; horns of medium length, spreading outward and forward, with the points upward. The colour of the skin is almost uniformly deep red, with face white, and a white patch on the shoulder. Sometimes they have the ridge white, with belly and legs of corresponding colour. There is a strain of blood where the animals are nearly white, with brown spots. For the dairy, the Hereford is the least productive of all the English breeds. The secretion of milk is at no time great, and the period of lactation is short. The cows generally suckle the calves, nearly the whole of which are reared. As animals for labour, the Herefords are admirably adapted, from their great weight in the yoke, their quick step, and their generally healthy constitutions, enabling them to undergo considerable fatigue. They are now little used for field-work; it is for their value as grazers that the Herefords are prized. When well kept, they are ready for the butcher at two and a half years, but are not generally slaughtered till they reach three to four years. The flesh is evenly laid on, and on the best parts, giving less coarse meat than perhaps any other breed. The flesh is highly esteemed; but when fully fattened, there is an excess of fat. Oxen of this breed always appear to great advantage at the Christmas fat shows. The Hereford has been long deemed the rival of the Short-horn, and in the county of Hereford, is asserted to be superior.

The *Devons* occupy the third place in the English agricultural prize-lists. They are smaller in size, and more delicate in structure than the Hereford. When reared on the richer lands of Somersetshire, the size is considerably increased. Specimens are met with nearly as large as Herefords. Their form is symmetrical; the head, small; the eye, clear and placid; the horns are finely tapered, spread out and upward; the horn is longer than in the Hereford. The colour of the Devon is deep red, without any white marking. As dairy-stock, they occupy a medium place, the milk being rather rich than abundant. There are dairies of Devons containing about 100 cows, which are stated to yield a large return of dairy-produce. As oxen for labour, the Devons are much prized; hardy, active, and quick steppers, they perform nearly as much work as ordinary farm-horses: the want of weight, however, operates against their working in pairs. As beef-producers, they are inferior to the Hereford; the quality of the meat is indeed superior, but it is unequal. This is a general complaint against the Devon in the London dead-market.

The *Sussex* breed is somewhat similar in form, and identical in colour with the Devon; it stands higher from the ground, and is less symmetrical. It is inferior for the dairy, but nearly equals the Devon for labour. They are long of arriving at maturity; but when fattened, the beef is of good quality. As a breed, they are not equal to the Devon.

The *Suffolk and Norfolk* polled breed is supposed to be descended from the polled Galloway. They are of medium size, somewhat deficient in symmetry, but are roomy and wide-set. The colour is dark red to yellow. The milk-vessel is large, generally well placed. The Sussex and Norfolk are much esteemed for their milking properties. There are also horned breeds almost indigenous to these counties. The colour is similar to the polled breeds, but they are inferior as milkers.

The *Long-horn* or *Lancashire* was at one time much sought after, especially after its improvement by Robert Bakewell. This breed is now almost wholly superseded by the Short-horn. The Long-horn is distinguished by the length of its horns; these are usually curved in the form of a half-circle, and are pointed downward. The length and general rotundity of the body, with the large sizes they attain, give this breed a fine appearance. The skin is usually thick, colours brindled, ridge and belly white, with marled spots inside the legs. The absence of early maturity, with their inferiority as milkers, has caused the breed to be neglected. In some parts of Ireland, and in the counties of Oxford and Derby, there are breeders who still maintain the Long-horn pure; but the greater portion of those exposed in public markets are crosses. In the two English counties referred to, the breeders of the Long-horn attach a high value to their herds.

The following facts are significant of the estimation in which the Long-horn was at one time held. For the purpose of comparison, selections are made from two public sales—one of Long-horns, the other of Short-horns. The sale of Long-horns took place on the 27th of March 1791, the stock being the property of Mr Fowler, of Little Rollright, Oxfordshire; the sale of Short-horns took place on the 11th of October 1810, being that of the celebrated Mr Charles Collings, county of Durham.

Lily,	3 years old,	410 guineas.
Countess,	9 "	400 "

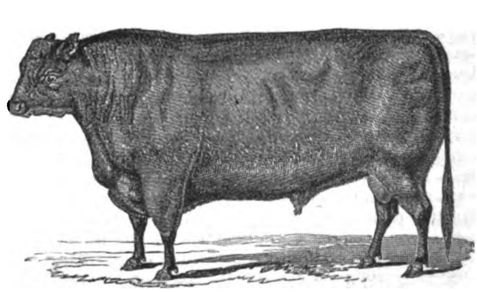
At Mr Page's sale, 14th of November 1793, Shakspeare, a bull (Long-horn), bred by Mr Fowler, was sold for 400 guineas; Mr R. Bakewell, in the spring of 1792, let a bull for four months for 152 guineas.

The *Alderney* is the most esteemed of the Channel Island cattle. They are delicate in form—colours varying from light red to fawn and dun—generally with white intermixed. The head is long and handsome; eye, large and prominent; horns, short and crumpled. As dairy-stock, they have been much lauded, particularly for the quality of the milk. One or two Alderney cows in a dairy are stated to impart a richness of colour to the butter. Such is the demand for cows of this breed, that it is believed a much greater number is annually sold in England than the Channel Islands produce. As the same breed exists in a part of Normandy, a portion of these may swell the number of the Alderneys sold in England. Dairymen in Scotland believe that either the climate of Scotland is too cold for the Alderney, or the qualities of the breed have been exaggerated. Where tried, they have seldom given much satisfaction.

In Wales, there are various breeds, but a family likeness pervades the whole. The most common are black in colour, of medium size, with the body long. The horns are of medium length, white, with black points, and pointed upwards. Like mountain breeds generally, they are active, hardy, and do not reach maturity till an advanced age. They usually stand well to the pail, but are not much esteemed as dairy-stock, except by cottagers. For labour, the Welsh oxen are only excelled by the Devon. Their hoofs are well adapted for travel, resisting the tear and wear of the most flinty and gravelly soils. In the counties bordering on Herefordshire, the cattle resemble somewhat the Hereford in form and colour, but are smaller in size, with less aptitude to fatten. The Pembroke and Glamorgan are the most esteemed. The former are generally dark brown, with white ridges. As milkers, both are superior to the Hereford. The Welsh cattle are much esteemed by the grazier. Droves of black Welsh may be observed grazing in fields over the greater portion of the southern counties of England; they are usually purchased in the Welsh markets at prices which may be considered moderate when contrasted with those paid for Herefords or for Short-horn crosses.

The *Ayrshire* is generally considered the most valuable for dairy purposes. It is of medium size; the horn is small, short, and bent inward, sometimes pointing upward. The body is long and low set; skin, thin, loose, and soft to the touch; the head, long and narrow at the muzzle; eye, large and lively, sometimes with a certain expression of wildness; the neck, long, and slender in the cow, with little muscle; the shoulder, sharp; the fore-quarters, light; ribs, well sprung; hind-quarters, long, wide, and deep; back, straight; legs, short; the bones, small, but joints somewhat loose and open. The udder is generally capacious, placed forward on the belly, and not extending backward beyond the buttock; the teats are wide apart, and generally small. To adapt them for the inferior pastures which is the character of nearly all dairy-farms in the west of Scotland, the young stock is kept in such a way as to stint them in growth. The Ayrshire, when reared in Ireland, or when treated liberally at home, is found to increase considerably in size; and if this quality were desired, by attention to feeding and selection, they could be reared to nearly double the weight that is generally esteemed the best for an Ayrshire cow. The heifers usually produce at little beyond two years, and are retained for the dairy till they reach seven or ten years. As beef-producers, the Ayrshires do not occupy a high place. When a Short-horn bull, however, is used, a very superior animal is produced for feeding purposes. This system is pursued by many farmers in the west of Scotland with great success, the stock being fattened off at two or two and a half years old, and realising nearly £1 a month for keep. The Ayrshire cow is more widely spread over Scotland than any other breed. Dairies of this breed occupy nearly the whole of the west of Scotland, from Wigton to Ayrshire. Taking Glasgow as the centre, a radius of thirty miles is nearly wholly occupied by this breed. The Ayrshire is exported to most continental states—Russia, Denmark, Sweden, France, &c.

Polled breeds.—Galloway, Angus, Aberdeen, &c., are peculiar to Scotland. The *Galloway* extends over a portion of the Border counties in the west of the island —Cumberland, Wigton, Dumfries, &c., and is named from the district of *Galloway*. In several of the south-eastern counties of Scotland, polled cattle are also found. They are there known as the Angus and Aberdeen polled. Fife, Kinross, and other counties produce some polled animals; but the Galloway, Angus, and Aberdeen polled cattle are the most generally esteemed. The polled cattle which are habitants of the east of Scotland, owe much of their present high character as beef-producing animals to several breeders, particularly to Mr Hugh Watson of Keillor, who, by a course of selection during fifty years, has, while increasing the size, given more



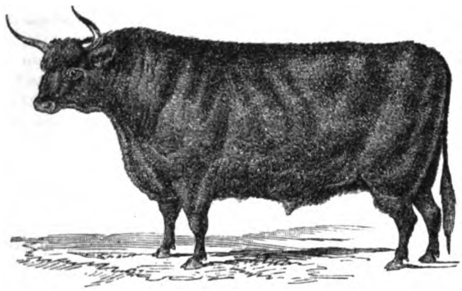
Polled Angus Bull.

symmetry, with greater aptitude to fatten. The above is a representation of a Polled Angus Bull, which was reared by this gentleman, and obtained the first prize at the Highland Society's meeting at Edinburgh in 1848. The polled Scots have all a family likeness; and the difference of climate between the west and east of Scotland accounts for the rougher coat of the Galloway. The polled Angus and Aberdeen are of larger size than the Galloway—nearly equalling the Short-horn; body, long and deep, but somewhat flat on the sides; skin of medium thickness; hair, short and glossy. The most esteemed colour is black. Occasionally, the udder and a portion of the belly are white marked. As milkers, the improved polled occupies a low place. As cattle for the yoke, they are equal to any British breed, being agile, quick-steppers, and hardy. They maintain their procreating powers to a longer period than any other British breed. There are several instances on record of cows breeding above the age of twenty years, and producing upwards of twenty calves. It is, however, as beef-producers that these polled breeds are so highly esteemed. A considerable portion are fattened in England; but as turnip-cultivation extends in the districts where they are

bred, the number which is annually fattened in the north is yearly increasing, almost the whole of which are sent direct to the London markets, live or dead. A cross between a well-selected Short-horn and these polled breeds produces superior animals—size, early maturity, and quality of flesh being combined.

In the counties of Aberdeen, Banff, &c., the horned breeds formerly bred, are gradually giving place to the pure polled, or crosses between the polled and Short-horn.

Highland cattle are much esteemed for the quality of the beef. The West Highland are the best known; they



West Highland Bull.

are found in the greatest perfection in Argyleshire and the Western Islands of Scotland. The above is a drawing of a West Highland bull, the property of Mr Duncan M'Naughton of Cashlie, which carried off the first prize at Edinburgh in 1848.* They are the most picturesque of all the British breeds; being handsome in form, straight from the head to the tail; body, round and symmetrical; legs, short and firmly set. The head is carried high; the forehead is protected by long shaggy hair; the eyes, large and lustrous; horns, long, spreading, and pointing upwards. The skin is usually thick, covered with a coating of shaggy hair, which protects them from the moist and stormy climate of their native hills. The colour is generally black; but they are to be found of all colours, from the light yellow or gray, almost white, to the deep yellow, red, and duns. The variety in colours heightens the picturesqueness of a herd of Highland cattle. They are at first small in size, but they increase rapidly when transferred to the rich pastures of the south, and are usually to be found grazing in the vicinity of gentlemen's seats. They are, as dairy-stock, distinguished for rich rather than for an abundant flow of milk. They do not continue in full profit for the same period as the Ayrshire cow. The calf is generally suckled where extensive herds of West Highlanders are kept. This breed can exist on the coarsest herbage, and maintain its footing where none of the other breeds would be safe.

Orkney cattle are of small size—colours black, or black and white. They are stunted in form, deficient in symmetry, and do not arrive early at maturity. The introduction of Short-horn bulls for crossing the native Orkney cow, will in a short time entirely change the character of the cattle sent from these islands to the mainland. Already the improvement in the stock sent out is very marked.

The Shetland Islands possess the smallest of the British breeds. When fattened, they seldom reach twenty-four stones of fourteen pounds. The colours are varied—brown and white, black and white, yellow, cream-colour, &c. As milkers, the Shetland cow, for the small quantity of food consumed, yields a large quantity of rich milk. The produce of a Shetland cow and Short-horn bull resembles the Short-horn closer than the Shetland; but they are generally disproportioned: they rapidly acquire flesh, and are not so suitable as the pure Shetland for a pet dairy cow. The cattle in Shetland, particularly during winter, resort to the sea-shore to eat sea-weed. They generally leave the mountain pasture for the sea-shore as the tide retires, and are seldom caught by the returning tide, although there have been occasional instances of animals being lost by the tide cutting off their retreat to the shore.

The *Kerry* is the only native Irish breed, and is confined to the western and more mountainous parts of Ireland. They are equally diminutive with the Shetland, are hardy, and can subsist on scanty fare. They are of various colours, but black is the most common in the Improved Kerry. They are well adapted for cottier holders in the mountain districts, yielding a considerable quantity of rich milk.

We have thus briefly treated of the breeds of cattle valuable in Great Britain. The most prominent, in general estimation, is the Short-horn. Of the breeds adapted for the dairy, the Ayrshire is the most esteemed; but the character of the climate, herbage, and local treatment, all influence the question of adaptability of breeds for particular districts or management. There are inferior animals of all breeds; and on fixing upon a breed, it is equally important to study to secure the best specimens, whether the object be for the dairy, or for the production of cattle intended for the shambles.

TREATMENT OF DISEASES.

Cattle are subject to various diseases, the result of improper treatment, or of causes connected with climate, which it is difficult to guard against. Many diseases can be traced to hereditary predisposition, such complaints generally proving the most obstinate to treat. By attention to feeding, shelter, and cleanliness, much can be done to promote a healthy condition. Cattle housed during winter in well-ventilated byres, or in open sheds, and partially sheltered during summer, are usually healthy. Certain breeds are naturally hardy, and can be kept in the open air during the whole, or the greater part, of the year; such cattle are comparatively free of those diseases which are induced by exposure to cold and wet. Cows confined to byres during the whole season, and fed to repletion, to induce an abundant flow of milk, are very liable to diseases of the respiratory organs. Cattle, when being fattened, are also subject to such inflammatory attacks. Veterinary surgeons usually prescribe bleeding and laxative medicines, and occasionally tonics. Recent experience in the treatment of inflammation of the lungs, particularly of pleura-pneumonia, has tended to shake confidence in the curative effects of bleeding—soothing rather than violent treatment being found the most successful. The owners of stock who can obtain, within a convenient distance, the services of an experienced veterinary practitioner, should employ such, rather than attempt to effect cures; but as certain complaints require prompt measures, the owners of cattle should be sufficiently informed, so as to be able to prescribe in such cases. All quacks should be discountenanced, and reliance placed on the curative power of nature rather than on the nostrums of the ignorant. Supernatural influences may tax the pocket of the superstitious, but will not effect cures. For the purpose of guiding the non-professional person, the following concise description of the more common complaints of cattle is given:

Choking.—Cattle fed on bulbous roots, such as turnips or mangold, are liable to accidents from swallowing a portion of a root without its being previously sufficiently masticated to pass down the gullet into the stomach. The animal ceases to eat, and stands apart from the rest of the herd. The distress of the animal, and the danger arising from the impacted substance, are in proportion to its size, form, and position in the

* We are indebted to the *Farmer's Magazine* for this and the Polled Angus Bull.

gullet. When it is fixed near the top of the gullet, the discharge of saliva, with efforts to regurgitate, is considerable. The head is occasionally extended, and the animal coughs frequently. By this, the obstruction is sometimes moved, and relief afforded. When the substance is fixed near to the entrance of the stomach, the discharge of saliva with eructations and coughing is usually absent. In both cases, the breathing and pulse become accelerated, and except the obstruction is displaced, there is considerable danger. The abdomen gradually distends, respiration becomes laboured, the pain increases, and the animal staggers, falls, and is suffocated. To prevent this, means are taken to force the substance downward into the stomach by the use of a probang. This, for an ordinary sized animal, requires to be about six feet in length, elastic, with a cupped knob on the end, somewhat rounded at the edges. If the probang is hollow, it admits of the escape of the gas. To operate, at least two persons are required; one to hold the head of the animal; the other, to pass the probang into the gullet and press the substance into the stomach. Lard, butter, or oil should be rubbed on the point of the probang; the operator taking hold of the probang, the tongue held with the left hand, or the assistant taking the tongue to one side, the probang being passed along the roof of the mouth enters the gullet. As it reaches the impacted body, firm but moderate pressure should be used. In using the probang, the head should be elevated, and kept in a straight line with the neck. When the resistance is great, care should be taken not to force the end of the probang past the obstructing substance, or to injure the gullet. The substance once moved, there is seldom any difficulty in forcing it down into the stomach. As the length from the muzzle to the entrance of the rumen is about six feet, the probang should be passed downward within a few inches of its entire length. Upon displacing the impacted substance, the gases collected, speedily escape, and the swelling falls. Sometimes it is necessary to puncture the rumen, to prevent suffocation. When this is done, the probang seldom requires to be used, as the obstructing body is gradually softened, and afterwards passes into the stomach. There are cases which can be relieved by giving the animal a dose of linseed oil or salt dissolved in water. But this treatment generally causes great pain to the animal, and there is some danger of a portion passing into the windpipe. Neither the probang nor the trocar should be used except there appears to be considerable danger, as there is always a liability to accidents in operating. Animals which have once choked, are liable to become again affected; and for some time they should have the roots grated, or other food substituted.

Hove.—This disease occurs during all periods of the year, but is more common in spring and autumn. *Hove, hoven, swollen, dew-blown, clover-sickness, fog-sickness,* are various terms by which a distended rumen is known. Hove may arise from a rapid swallowing of the food followed by the sudden repletion of the stomach; or it may proceed from a deranged state of the digestive organs. In either case, an evolution of gas takes place, which, if not speedily neutralised, or means used for its liberation, causes death, generally by suffocation. Sudden changes in the diet are liable to cause the disease. In spring, when animals which have been confined to courts or byres, are turned into fields where the herbage is luxuriant, with a considerable portion of clovers, they are liable to swell. The liability is increased when the grass is damp from hoar-frost, dew, mist, or rain; also when there is a breeze more or less strong. In summer and autumn the danger is increased when the cattle are placed upon second-crop clover, or allowed to graze on stubbles, where the young clovers are advanced. Cattle getting into a field of beans or peas when these are in a succulent state of growth, are liable to hove, particularly if the crop is damp. Cows which are removed from their pastures to be milked, are more liable to hove than cattle allowed to remain at pasture. Hove occurs occasionally during winter with cattle being fattened on turnip. Swedes which have been mildewed are very liable to produce this state. Partaking of bean-meal along with turnip generally increases the tendency to hove. The disease is frequently sudden in its attack, requiring to be combated speedily, or the animal may be lost. When the distension is not so far advanced, ammonia in water, or lime-water, should be given. Alcohol has also a good effect. Tar placed in an egg-shell, and passed by the hand over the throat, usually gives relief. One to two ounces of turpentine added to a quart-bottle of linseed oil generally reduces the swelling. One ounce of hartshorn, with four drachms of powdered ginger in a pint of water, may be given, or two drachms of chloride of lime dissolved in a pint of water. If the distension is so far advanced that the animal is suffering considerable pain, and moves with difficulty, an incision into the rumen should be at once made, if relief is not afforded by medicine. The delay of a few minutes may prove fatal. An incision made with a sharp-pointed penknife, or with a trocar, will give speedy relief—the instrument passed inward and downward to puncture the rumen. If a knife is used, a quill may be inserted in the wound. It is all-important to remember that the incision should be made on the left side, in that part of the abdominal cavity between the last rib and the point of the hook-bone. After the escape of the gas, the wound may be drawn together by a needle and thread, or piece of sticking-plaster placed on the part. The feeding afterwards should be restricted in quantity. If the patient exhibit symptoms of constitutional disturbance, aperient medicine may be given. One pound of common salt, or an equal quantity of Epsom salts dissolved in water, is the most suitable.

Abortion occurs more frequently in the cow than in any of the other domesticated animals. When one cow of a herd aborts, the case is usually followed by others; and the cow which has once slipped calf, is extremely liable to subsequent abortion at the same period of gestation. The character of the food (such as pastures or forage affected with ergot), fright, violent exertion (as in leaping fences), disease such as pleura-pneumonia, and other causes, tend to produce abortion. When it takes place at the early stages of gestation, the constitutional disturbance is seldom great. Occurring, however, after the fifth month, there is considerable danger from inflammation, particularly of the womb. It is advisable to give sedative medicine: the best is common salt in the drink of meal-gruel. The food should be restricted, and the cow kept quiet, being previously removed to a comfortable loose house, and away from the other cows. Unless the animal is valuable for breeding purposes, it is advisable to fatten her off. If, however, it is determined to retain her, she should be got into good health previous to being served; and after she is pregnant, she should be kept quiet, fed regularly, but rather sparingly. Some practitioners recommend that within a few days of the period of the former abortion, four quarts of blood should be taken from the neck, and one ounce of the tincture of opium given each alternate day for a week. Keeping the animal in an open shed, and studying quietness, is the best security that the cow will reach the full time.

Puerperal fever occurs frequently where the cow is in high condition, the flow of the lactic fluid considerable, and where parturition has been protracted and severe; but very frequently it arises from overfeeding previous to and after parturition. The cow, when affected, rises with difficulty—sometimes is unable to get up—the flow of milk is nearly, if not wholly suspended; and if relief is not speedily afforded, the animal dies. The first duty of the practitioner is to act upon the bowels—one pound of Epsom salts, with

two ounces of ginger, dissolved in water, should be given. This may be repeated in four hours. Clysters may also be tried. The udder should be bathed, and every effort made to induce a flow of milk. No time should be lost in calling in the most skilled practitioner.

Garrot in the udder sometimes follows severe parturition. It is, however, more frequently produced by an excessive flow of the lactic fluid to the udder previous to calving. It also arises from an unskilled or careless milker not drawing the teats regularly, nor emptying them completely. If the udder is much distended previous to parturition, the cow should be milked, and this for several days. Not only is this a great relief, but it tends to check that febrile condition incident to the constitutional disturbance. The indications of garrot are, a hot udder followed by a hard knot, after which pus and blood are mixed with the milk—this generally from one teat. Occasionally an abscess forms on the outside. Upon the first symptoms being observed, the cow should receive a handful of salt in gruel or in boiled food; repeat it every time the cow is fed till the bowels are acted on—the quantity of food restricted. The udder should be bathed with hot water, and gently rubbed, and the teats emptied. A little lard rubbed over the udder is also advisable. This should be attended to each time the cow is milked—three times in the twenty-four hours. If the garrot proceeds to form pus, the affected teat should be drawn regularly, and the matter coming from the teat kept separate from the rest of the milk. The endeavour should be to preserve the teat, by preventing it closing up. A cow with a light or blind teat cannot be disposed of as a sound animal, although the quantity of milk is seldom much impaired. When two quarters of the udder are affected, the result is different.

Diseases of the skin are not common in cattle that receive ordinary attention as to housing, cleaning, and feeding. *Mange* is produced either by contagion or by poverty of condition, arising from neglect. A mixture of oil and sulphur should be well rubbed into the roots of the hair. The animal should receive one pound of common salt each alternate day till the bowels are operated upon—bran mashes, roots, or green food allowed. As the disease is contagious, the patient should be separated from other cattle. *Lice* is a much more common complaint than mange; indeed, these parasites are seldom absent from cattle kept in byres or open sheds during winter and spring. Contact, direct or indirect, with animals affected, inattention to cleanliness in byres and cattle-courts, and, some believe, exposure to wet, with low diet, cause the presence of lice in cattle of all ages. Several recipes are in use; tobacco-juice, with spirit of tar, is the most common; a salve composed of mercury and lard; also soft soap and oil mixed with sulphur. Oil well rubbed into the roots of the hair, where the larvæ or lice appear, is the best treatment. The oil closes the breathing organs of the parasites, and thus speedily kills them. The skin should be well curried, and the parts to which oil has been applied may be washed with soft soap and water, followed by rubbing with dry wisps. The byre or sheds should be gone over with lime-water, to destroy any of the larvæ in the wood-work or stone walls.

Red-water occurs frequently during spring and towards the end of autumn among cattle grazed on low damp situations, subject to hoar-frost. It also occurs during summer, when the season is dry, with heat and cold alternating. The disease is confined chiefly to young animals, or cows that have recently calved. Red-water has been attributed to sudden chills; the animal exposed to the sun's rays during the day, lies all night on cold ground, while the temperature falls below the freezing-point. The disease is connected with a deranged state of the digestive organs, principally of the liver. The first symptom is diarrhœa, with loss of rumination; this is followed by constipation; the fæces also become black, and the animal rapidly loses condition; and if in milk, the secretion almost wholly ceases. The disease should be treated with calomel. The following may be given in oatmeal gruel: Calomel, one and a half scruples; carbonate of ammonia, four drachms; sulphur, six ounces; sulphate of magnesia, six ounces. After the animal is convalescent, exposure to cold or extreme heat should be avoided.

Chronic diarrhœa is common to cows that have been improperly managed when young; it is also hereditary. The disease is generally, however, the reiterated application of causes seldom suspected at the time, till the constitutional disturbance shews itself. The animal loses condition. Diarrhœa is frequently the concomitant of other diseases, consumption being the most common. With cows turned out daily during early spring, or kept late in the season at pasture, receiving little house-feeding, the scanty fare in the fields, with the cold and wet, causes diarrhœa. The local terms of *wasting*, *consumption*, *rot*, *scouring*, &c., all indicate a state of disease, which, if not checked, ultimately causes death. In dairy districts, the complaint occasionally carries off a great number of cows. Calves are also subject to scour, arising from a derangement of the stomach. Carbonate of magnesia, two drachms, may be given to a calf: for cows and young cattle—calomel, two scruples; opium-powder, half a drachm; chalk, three ounces, mixed in gruel. It is sometimes advisable to empty the intestines by a dose of salts. Half a pound of Epsom salts may be given—this followed by calomel and opium, half a drachm of each given daily.

Quarter-ill, *black-leg*, *felon*, *shewt of blood*, &c., are local names for a disease of an inflammatory nature, to which young cattle are exceedingly disposed, unless their condition is kept up and their comfort otherwise studied. Sudden in its attack, and rapid in its progress, generally terminating fatally, all that can be successfully attempted is *prevention*. The animal is observed to be lame; the affected limb when examined is found swollen; the skin over the part, when pressed, gives a crackling noise; exudated bloody serum is collecting in the cellular tissue. The inflammation proceeds; mortification ultimately ensues; and the animal usually dies within a few hours after being observed to be unwell. Calves weaned and kept late in the season at pasture, in fields exposed to the prevailing winds or to the miasma of a marsh or damp ground, with the herbage hard and deficient in nutriment, are extremely liable to become affected, either during the period or within some months after they are removed. When the disease appears after the removal, the feeding has usually been improved in quality. A sudden change in the flow of blood causes a febrile condition, followed by congestion in one or other of the limbs—in some cases, in the brisket. An extrication of gas, followed by serum, in the cellular membrane, and, if the animal survives, extensive sloughing of the skin, take place; but sloughing is so exceptional, that few practitioners have witnessed a cure. When one animal of a herd becomes affected, the patient, as well as the remainder, should be bled; the intestines relieved by a dose of salts, from one quarter to one pound of Epsom salts or common salts. With those not affected, the supply of food should be regulated so as to prevent a rapid formation of blood, because the weakened condition of the system is unequal to carry on a rapid organisation of the frame. The bowels should be kept in a healthy state: to secure this, allow oil-cake from two to five pounds daily. The disease is confined to young animals; and is rarely known to attack those which have reached two years.

Catarrh, *cold*, *cough*, is often induced by exposure to cold and wet, occurring mostly in spring, when the wind is easterly. Inflammation of the mucous membrane of the air-passages which line the nostrils, causes a slight cough; the throat is usually affected, the coat staring. If the cough is short, husky, and dry, and the animal

looks anxious and haggard, the inflammation has extended to the lungs; bronchitis is present, a dangerous disease, requiring the aid of the most skilful veterinary surgeon. Catarrh is not unfrequently manifested as epizootic. Fever is invariably present, but not always of the same character; sometimes of a low typhoid kind; in other cases, active. When one animal of a herd becomes affected, it should be separated, being placed in a warm but well-aired house; bleeding, with aperients and counter-irritation, employed. Those not apparently affected, should receive a dose of common salt, the throat being rubbed with a stimulating liniment. Cake should be allowed; if previously given, the quantity should be increased, and the animals protected from cold, and especially from wet. If they are confined to an ill-ventilated byre, a portion should be removed to another place, the ventilation improved, and cleanliness strictly carried out. The disease is so subtile, that unless the greatest care is taken, a portion may be expected to succumb. Some practitioners insert a seton in the dewlap as a preventive of this as well as of quatrer-ill.

When *inflammation of the lungs* sets in, there is quick and laborious breathing, occasionally accompanied with a low noise; cough, short and painful; the pulse is sometimes full and strong, but is frequently weak; the nostrils are dry and red, the mouth hot, the eye dull; the skin is cold to the feel, and the hair partially staring. The rumination almost wholly ceases; condition is rapidly lost; and except the disease is checked, the animal, gradually becoming weaker, dies. Bleeding in the earlier stage, the bowels opened and kept active, counter-irritants applied to the sides immediately behind the armpits, are the only means at command, but they seldom prove successful in the treatment of cattle. The most insidious, and, at the same time, the most extensively fatal form of inflammation of the lungs, is

Pleuro-pneumonia.—There has been difficulty in tracing this epizootic pestilence. It was first experienced in England in 1842, and in Ireland at least a twelvemonth previously. Introduced, it is stated, from the latter to England by a lot of half-starved cattle, the disease rapidly spread over several of the dairy counties —Cheshire, Shropshire, Staffordshire, and Middlesex suffering most. Since that period, the annual loss from the disease exceeds perhaps any estimate that has been made. Its ravages have been most extensive in ill-ventilated, crowded cow-houses. Town-dairies suffer most severely, pleuro-pneumonia sweeping off in a few months almost the entire stock—sometimes absent for weeks, and returning with aggravated symptoms. In rural districts, the disease may be found on one farm, those in the neighbourhood being free. Frequently, however, these are afterwards affected, although there are farm-places, and even districts, where the disease has never appeared. Professional opinion is divided as to its contagious or non-contagious character. Farmers, however, generally believe that it is contagious, and strong evidence has been adduced in support of this belief. The virulence is known to increase with the absence of cleanliness and with over-crowding, especially in swampy and marshy districts. The disease is seldom observed by those in attendance on the stock till it has reached the second stage. The earlier symptoms are a slight cough, breathing laboured, the coat staring, and dulness, with general depression. These tokens frequently depart for a time, returning generally in a few days with increased force. The breathing is then accelerated, the cough becomes more painful, the animal moves unwillingly, looks dull, the eye anxious, the appetite and rumination impaired. In the third stage, rumination is suspended, respiration short and catching, the belly tucked up, the cough still more husky and painful; the anxious expression is followed by the eye becoming glassy; condition is rapidly lost; the animal breathes with difficulty, and dies from suffocation, or from general prostration.

Various remedies have been tried to combat the disease; bleeding was at first recommended as the sheet-anchor. When bleeding was practised at the second stage of the complaint, it was observed rather to hasten than to retard the crisis. Inoculation, as a means of prevention, was much lauded for a time, and its efficacy is still believed in by owners of stock in Holland, Belgium, and parts of France. In England, it never found many advocates. Arsenic and other powerful medicines have been all recommended, experimented with, and found inefficient. The general practice is now, both with cows and feeding-stock, upon the first appearance of the disease, to dispose of them for slaughter. Sometimes, however, treatment is attempted, but generally with little success. If the disease is observed in the first stage, blood should be taken, the throat rubbed with a blistering liniment, the bowels acted on by salt, and green food should be given. The febrile symptoms checked, tonics, sulphate of iron with manganese, should be given, a small portion of nitrate of potash added, and the animal kept in a well-ventilated place, all draughts being avoided. If the patient is a cow in milk, convalescence is more doubtful, this disease being extremely fatal with dairy-stock, particularly those in full vascular condition. If the disease has reached the second stage, bleeding is seldom advisable; dependence should rather be placed on acting on the system through the bowels, and by keeping up the system by giving sedative medicine, nitrate of potash, tartarised antimony; also tonics, drinks, and green food, the blood being kept to the surface by gentle friction of the skin and sheeting. Abortion generally follows this second stage, and the cow sometimes recovers almost immediately after the fetus is expelled. If recovery follows, the condition of the cow should be advanced previous to the service of the bull, and the after-health of the animal studied. The disease will have destroyed a portion of the respiratory powers of the animal, and, except she is very valuable for breeding, she should be fattened and disposed of to the butcher. An animal which has suffered from a pulmonary affection should not be fed on forcing food, whether for fattening off, or retaining as a breeding or dairy animal, as there is some danger of the disease being again developed. Indeed, the greatest care is required to avoid a new outbreak. Cold, damp, and foggy weather, particularly with occasional gales, appears to hasten the development, if not the generation of the disease. As the disease is both epidemic and contagious, the employment of every precautionary measure is the more necessary.

Excrema, fever in the feet, foot disease, mouth disease, vesicular epizootic, epidemic, &c., are terms for a disease which is highly contagious, as well as epidemic. It spreads rapidly through the whole herd, and may be communicated to animals of a different species—sheep, pigs, poultry, &c. This complaint was unknown in Great Britain previous to 1839. The first symptoms are a cold shivering fit, the body trembling and parts quivering; the whole being cold, especially the extremities. There is a discharge of frothy saliva from the mouth; food is refused, and rumination is suspended. The cold is followed by reaction; the extremities become hot; the muzzle dry; the mouth, hot and sore; tongue, swollen; vesicles appear on the tongue, lips, and other parts of the mouth. The animal becomes restless, sometimes shaking the legs with violence. The hoofs suppurate; blisters form at the union of hair and hoof, and between the toes, and pus is sometimes discharged from the openings. The animal becomes very lame, walking with difficulty, and placing the heels first on the ground. The disease usually runs its course in seven to fourteen days, terminating favourably. There are cases, however, when the animal is unable to rise, and there is a general prostration of strength; and except the animal is nursed, and care otherwise taken, death follows. The general treatment

should consist of a dose of salts, one pound; sulphur, four ounces. The feet should be bathed, and if the animal is down, they should be poulticed, and the hoofs pared close. If blood exudes from the toes, the recovery will be more speedy. Dress afterwards with an astringent lotion; and if proud flesh appears, a stronger caustic must be used. The laxative medicine should be followed by tonics—sulphate of iron, two drachms; ginger, two drachms, given daily. Oatmeal gruel, given by a horn, if the animal will not drink—poured down the throat not less than three times daily—and green food or sliced roots offered. Every means should be used to keep up the system, as the disease is generally accompanied by great prostration. Upon the first appearance of the disease, it was regarded with great alarm—stock lost condition; and where care was not taken, death occurred. The disease is now much more mild, less frequent, and is not a cause of much anxiety.

Murrain, steppe-murrain, rinderpest, pest bovine, typhoid bovine, &c., are various names for the same disease. In the steppes of Southern Russia, and in parts of Austria, the disease, it is stated, is constantly present, extending occasionally into other districts, communicated by affected animals travelling northward and westward from the breeding districts. The number of animals which have died from this disease during periodic outbreaks is almost fabulous. In Russia and Austria, prompt measures are now taken to prevent the spread of the disease; not only the affected animals, but all cattle they come in contact with, being destroyed. It is supposed by the best informed German and French veterinary authorities, that, by adopting the measures used in those districts where the disease is constantly prevalent—namely, slaughtering all affected animals, and indemnifying the owners—the disease could in a short time be wholly eradicated. This, or a disease similar in its character, called the murrain, was experienced in the British Islands during the latter half of the last century. It appeared first about the year 1745, and continued its ravages for several years; in many parishes, nearly the whole cattle were swept off. In the early months of 1857, considerable alarm was felt lest the steppe-murrain of the continent should be introduced into this country by animals from the Baltic ports. To guard against its introduction, an Order in Council, prohibiting the importation of cattle, hides, &c., from certain of the Baltic ports, was issued. Recent information shewed that the alarm was caused by exaggerated reports of the condition of the cattle in parts of Prussian Poland. The prompt measures adopted in Prussia have prevented the disease spreading. The diseased animals were destroyed, and a military cordon established, preventing all communication with the affected districts.

There are several other diseases to which cattle are subject, but as they are exceptional rather than common, a description is not deemed necessary. Consumption, chronic dysentery, tumours, with tendency to catarrh and scrofulous complaints, are indications of a constitutional predisposition, which unfits the animals for breeding purposes, and also for the dairy, particularly where the milk is used as food.

FATTENING FOR MARKET.

Rules for Selecting Cattle.

In selecting cattle for *feeding*, the first point is to fix upon the breed suitable for the character of the accommodation, and for the food intended to be supplied—also, whether for winter or summer feeding. The next consideration is the age, and certain indications as to the fattening qualities of individual specimens or lots: those animals whose forms are symmetrical, having the back straight, ribs well-arched, chest deep and full forward between the fore-legs, quarters long and broad, legs rather short than long, the joints being large, fatten rapidly. But the most certain indication of a quick feeder is the touch—a soft, mellow, vascular skin with a covering of silky hair. The character of the horns, when these are present, also indicates the feeding qualities. The horn differs in the sexes, castration producing a great change in its form. In all cases, the horns should be placed wide rather than close, growing outward and forward.

To judge of the age of cattle by outward signs, considerable experience is necessary. The dentition is the most certain guide; still, there are considerable variations, due in some measure to such causes as feeding and the peculiar breed. Professor Simonds has found, from a long series of observations, that the following are the averages of the appearance of the incisor teeth:

Average of Early Dentition.		Average of Late Dentition.	
1 year 9 months	to	2 y. 3 m.	Two permanent incisors.
2 years 3 "	"	2 " 9 "	Four " "
2 " 9 "	"	3 " 3 "	Six " "
3 " 3 "	"	3 " 9 "	Eight " "

The dentition is completed about the fourth year; consequently, a four-year old animal will be full mouthed. The incisors, as they flatten and wear on the surface with a diminution of size, indicate the age—the incisors which first appeared changing first, and being followed by the second, third, and fourth pair of incisors. The horns also indicate age, rings appearing each spring. The first ring appears at three, sometimes, however, at two years, particularly in the female which has produced. In the market for dairy-stock, the use of the file and sand-paper is sometimes traceable on the horns of middle-aged cows.

Methods of Housing and Feeding.

Cattle are fattened for market by several methods. Besides grazing in the fields during the season of grass, they are fattened in courts or boxes, receiving regular supplies of green food—grass, tares, &c. Usually, cake and corn are given as auxiliaries. During winter and spring, cattle are prepared for market in open sheds, loose boxes, and byres—fed upon hay, roots, cake, and corn. Consuming turnip in the field by cattle is now seldom practised. Summer-feeding in sheds, loose boxes, and byres, has been much advocated; but the system does not gain ground rapidly. Cattle placed on permanent pasture producing rich herbage, make greater and more uniform progress than cattle confined to courts, boxes, or byres. There is always considerable difficulty experienced in obtaining a regular supply of succulent food; and unless cake, or cake and corn, are given, cattle do not fatten rapidly in confinement. On arable farms, without any portion in permanent pasture for cattle, soiling presents many advantages. By cutting the mixed grasses for feeding cattle, a greater number can be kept on a given space, the manure-heap is increased, and the after-crops, where the grasses have been cut, are superior. To carry out the system successfully, a supply of tares, if not of lucerne and sainfoin, is advisable; also water at command, regular feeding as to time and quantity, and increased allowance of concentrated food—such as cake—as the animals improve in condition. For calves, year-old cattle, and other animals not being prepared immediately for the fat market, soiling is advisable, combining economy of food with protection from exposure to sudden atmospheric changes. To secure the full advantages of soiling, good ventilation, cleanliness, quiet, and regularity in feeding, are indispensable.

It is in the winter-feeding of cattle that the greatest difference of opinion exists among practical men, both as to the mode of housing and the manner of feeding.

Fold-yards with sheds is the most common method of housing. When these are constructed so as to divide the cattle into small lots, and the shedding is ample and comfortable, cattle are found to make equal progress with those confined in byres or loose boxes, provided

the climate is not severe. Where the rain-fall is excessive, and where the cold, either from altitude, exposure, or latitude, is considerable, cattle make greater progress confined in byres or in loose boxes.

Stall-feeding is the common term where the animals are fastened up in stalls or tied to stakes. From the restraint preventing exercise, young cattle, one and two year-olds, generally suffer from diseases of the joints after they have been kept in one position for two to four months. When the knee and hock joints become inflamed and swollen, further progress is arrested, and the animal requires to be placed in a loose box or open shed, to recover. If the removal takes place upon the first appearance of joint disease, the rate of progress is little checked; but when delayed for one month or more, the animal seldom recovers so as to repay the value of the food consumed in fattening. The advantages of stall-feeding consist in the economy of house accommodation and of food, and in the equal distribution that it secures of concentrated feeding-substances.

Box-feeding has lately been much advocated. When the boxes are properly constructed, and the comfort of the animals otherwise studied, this system presents, on the whole, advantages which neither of the more common methods possesses. The cattle are placed either singly or in pairs. When single, the divisions are usually spars, to admit of the animals seeing one another. Spars being more economical than walls of stone or brick, are the more common division, even when two or more cattle are placed together. The advocates of box-feeding assert, that besides the warmth and shelter provided without the restraint of the stall, there is economy of straw used for litter; and the manure is very superior to that produced in open courts or from byres.

Board-feeding has also been advocated by Mr Mechi and others. But cattle kept on sparred boards do not advance in the same ratio as cattle kept in loose boxes or open sheds, with their comfort secured by well-littered beds—the feeding and other conditions being similar.

The methods of feeding present even greater diversities than the systems of housing. In England, the practice is rather to restrict the consumption of roots; while in Scotland, turnips are given without stint. In the former, hay is the usual fodder; in the latter, straw.' Without pursuing the difference in practice further, the following are the outlines of the more common methods of feeding:

In England, cattle, which are well advanced in condition on grass by the end of autumn, are removed to the farm-offices, the period of housing being in part determined by the condition of the grass. Hay is placed before them, and a limited allowance of tares, second-crop clover, or turnip, is given. Cake is also furnished. If the cattle are intended for sale in the Christmas markets, the allowance of cake is large—six to fifteen pounds daily are common, particularly for large cattle of the Short-horn, Hereford, or Devon breeds. Cattle not advanced in condition are kept longer in the field. When removed to *hammels*, fold-yards, byres, or boxes, the feeding for some weeks consists of hay with roots, generally turnips of the soft varieties. Sometimes the roots are given whole, but the more general practice is to cut or to slice them. For this purpose, several implements and machines are in use. Latterly, machines for pulping the roots have come into considerable request. The most recent and most highly approved system of preparing the food, is to cut the fodder—a mixture of hay and straw—and to reduce the roots by a pulping-machine. The cut fodder and the pulped roots are mixed together, and afterwards given to the stock. Some feeders advocate that the mixture should be allowed to lie in a heap for some hours before it is put into the feeding-troughs. Besides the mixture of fodder and roots, the adding of dissolved linseed or cake, made into a jelly, is practised, and with the best results. The economy of roots is so considerable that the consumption is reduced to fully one-half; and the progress obtained is the maximum.

The most general practice is to house cattle in October, and to commence feeding with the softer varieties of turnip; these, continued up till the month of January, are followed by Swedes or mangel-wurzel. Cake or corn is allowed; sometimes a mixture of the meal of barley and beans is given along with oil-cake, equal weights of each. As the condition of the animals advances, the allowance of cake, corn, &c., is increased. Commencing with three pounds, the allowance is augmented to ten pounds daily.

The quantity of roots an ox will consume depends in some measure on the age, condition, and size of the animal, but especially upon the quantity of auxiliary feeding-substances given along with the roots. An ox which, when fattened, will weigh 60 stones of 14 pounds, will, with straw as fodder, consume of white turnip, 160 to 180 pounds daily; of Swedes, 120 to 160 pounds; of mangel-wurzel, 100 to 140 pounds. When the roots are reduced to thin slices, or are pulped, and then mixed with chopped forage, the consumption of roots will diminish about 25 to 40 per cent. When the allowance of concentrated feeding-substances amounts to five pounds daily, the reduction in the weight of roots is about 10 per cent. With auxiliaries to the weight of ten pounds daily, the quantity of roots eaten is reduced by 30 to 50 per cent., when cake and cut forage are allowed.

With hay as forage, the consumption of roots is rather less than when straw is given; but as hay and straw both differ so much in quality, the relative proportions and the relative influences differ considerably. Some assert that turnips are the cheapest of fattening substances, the quantity being unrestricted, and straw allowed as fodder; on the other hand, there are others who maintain that cattle cannot be fattened on turnip and straw, and that it is economical, both as to time and the consumption of roots, to give hay, with cake and corn in addition. Present practice, influenced in part by the high rates for beef, is to allow a certain quantity of cake, corn, or a mixture of both; the roots sliced or otherwise prepared, the cake broken, and the corn ground into meal. As previously stated, the practice of the English feeder is to use hay as fodder; of the Scottish feeder, to give straw only as fodder, along with roots. Both fatten cattle at nearly the same rate of advance, which is, on an average, about two pounds of live weight daily. This is taken to represent the increase in beef. When auxiliary substances are given, the rate of progress reaches about three pounds daily of live weight. In Scotland, the usual estimated period of fattening an ox is five months; this period is shortened by the employment of auxiliaries—cake, corn, &c. In England, the period of fattening is somewhat longer; but the English feeder prefers to mature the cattle more perfectly than the Scottish feeder usually does.

DAIRY HUSBANDRY.

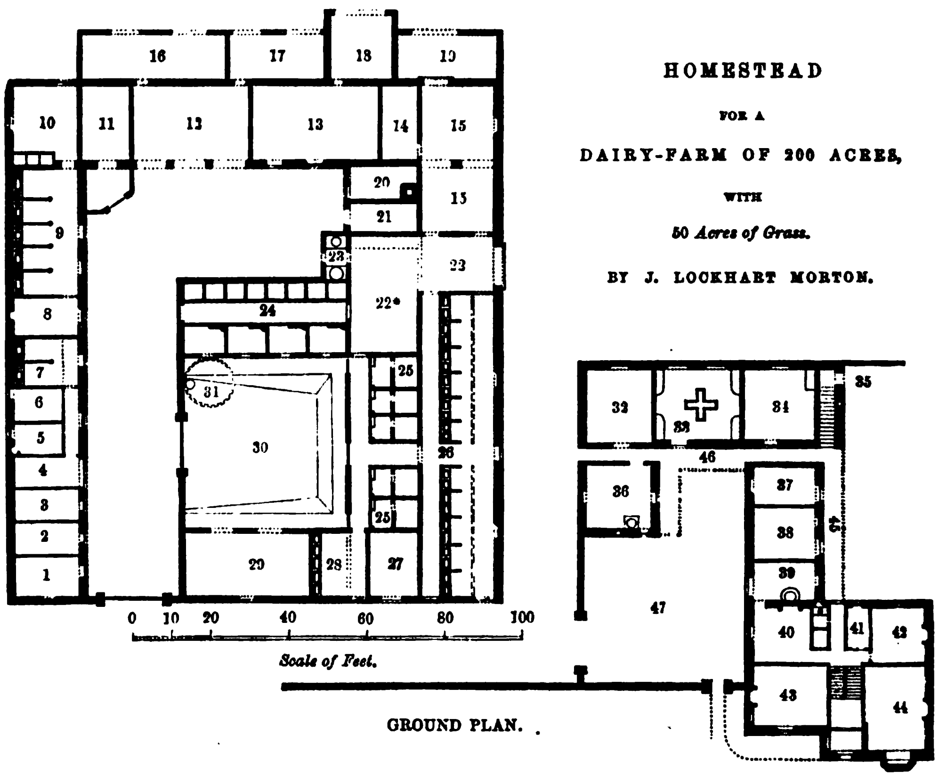
Dairy husbandry is generally practised in low-lying districts, with an argillaceous soil, producing nutritious herbage. Occasionally, dairy-farming, combining the rearing of cattle, is followed in upland and moorish districts, unsuitable for sheep or for arable husbandry, and the fattening of stock. Dairy-farms in England are most frequently to be met with in Cheshire, Gloucestershire, Wiltshire, Lancashire, Leicestershire, and the counties of Devon and Somerset; in Scotland, in the counties of Ayr, Renfrew, Lanark, Dumbarton, Stirling, Linlithgow, Wigton, and Kirkcudbright. In Ireland, the best dairy-farms are to be met with in the southern counties, the best quality of butter being shipped at Cork.

A well-arranged homestead, having every convenience to accommodate the cattle, and to store and prepare their food, is of essential importance in a dairy-farm. In the annexed figure, we give the ground-plan of one adapted for a farm of 250 acres, designed by J. Lockhart Morton, 26 Parliament Street, Westminster. The external view is given in our frontispiece.

An excellent arrangement for a dairy-farm steading will be found in Mr Stephens's elaborate work, *The Book of the Farm*, vol. ii., p. 289.* This plan was carried out in practice, and was found to possess all desirable conveniences.

Cow-houses—Cleaning.

Cows cannot be profitably maintained unless they are treated carefully, and their comfort secured as to house accommodation, feeding, and cleanliness. They should be kept during winter in roomy, well-ventilated byres; and in summer they should be protected against cold, damp, and heat. To secure these conditions, the byre should be occupied part of the twenty-four hours during all seasons of the year. The cows should be kept as free as possible from all extraneous annoyance; as flies, skin-irritation, &c. Many of the points to be attended to in the construction of stables (see No. 38, The Horse), are of equal importance in that of cow-houses; damp should be prevented, and a good healthy atmosphere secured.



HOMESTEAD FOR A DAIRY-FARM OF 200 ACRES, WITH *50 Acres of Grass.* BY J. LOCKHART MORTON.

Single stalls are preferable in almost every point of view to double. The cows are more easily milked, and not so troublesome or restive as when confined with a neighbour. The division between the stalls—or the *travis*, as it is termed—should be of wood; but stone is commonly used in Scotland. In the majority of byres, travises are absent, the cows being tied to a stake—a round post of wood fixed in the ground at the one end, and above to a wooden beam, which passes the whole length of the byre, with the ends built into the walls. For floors, see our remarks on stables in the number on The Horse. The manger should not, as is frequently the case, be on a level with the floor.

There are various ways of binding or fastening cows to the stall. The *baikie* is objectionable, as it only allows of one position being maintained. The seal is

* Blackwood and Sons, Edinburgh and London.

said to be the best. This consists of a chain or ligature provided with a hook and clasp for retaining it round the neck of the cow; the other end terminates in a ring, which is allowed to slide up and down a post placed in an inclined position at the head of the stall. The lower part of the window should be made of two shutters, the upper part glazed. Where a number of cows are kept, the *byre* or *shippen* should have a central passage, the stalls being arranged right and left of this, with smaller passages between the rows of stalls. In this way, the cows lie in the direction of the central passage, and at right angles to the smaller passages. The cows lie tail to tail, so that the dung from the cattle of the two rows of stalls is easily removed. In some byres, there is a passage in front of the cows, affording facilities for feeding, &c. In a few instances, the byres are so arranged, that the cows stand with their heads to one another, a passage between them admitting of feeding. This form is common in districts of Holland. The root-house should be at one end of the byre.

GENERAL MANAGEMENT.

Dairy-stock.—To insure the perpetuation of valuable qualities in cows intended for the dairy, it is necessary to breed from good bulls of a variety similar to the cows. Cross-bred animals are frequently good milkers, but it is not deemed advisable to continue to breed from such. As the form of the milk-vessel and the milking qualities descend from the sire rather than from the dam, it is important to select bulls of good parentage on both sides. The heifer, if properly fed, should begin to breed at two, or not beyond three years old; the cow is at her prime at from four to seven years, and falls off by nine to twelve years, at which age it is customary to fatten her for market. In selecting cows for a large dairy for supplying milk for town-consumption,* a preference is usually given to cows that have had their third or fourth calf. The period of service of the bull varies considerably; breed, mode of feeding, &c., all influence the time a bull can be kept for service. In the more highly improved breeds, such as the Short-horn, one year-old bulls are preferred by some. Occasionally, superior animals are kept till twelve years. In ordinary breeds, such as the Ayrshire, Polled, and Highland breeds, the bulls are reserved till they reach two years, and retained till the age of four, or seven years.

The period of gestation in the cow is liable to very considerable variation; the average period is about nine months two weeks. A calf is most likely to survive and be healthy which has been carried the full time. Calves have survived that were born in the seventh month, also those that were calved in the eleventh month. Heifers come into season generally when about fifteen months old; there are instances of Short-horn heifers being impregnated at seven months. The age at which they take the bull is regulated by the breed, and in a special manner by the food. Heifers and cows come into season at different periods of the year; but spring, summer, and autumn are the more common periods. The cow remains in season about twenty hours. The periodic return is from three to four weeks, except she is impregnated. Once impregnated, the desire ceases, if the animal is in health. After parturition, the cow, if highly fed, will come into season in three weeks; with ordinary keep, the period may be six or more weeks. Under a very low diet, or in low condition from disease, the cow does not come into season till the flow of milk is considerably diminished. In the Shetland Islands, to be in calf one season, and to be farrow next, is not an uncommon occurrence.

The period during which a cow will yield milk depends, in some measure, on the feeding. If not in calf, the flow of milk may be kept up for several months beyond the average period, which is nine to ten months. There have been instances of cows milking well the second season, and falling little short in quantity of those having had calves; but these cases are exceptional. Heifers that had never been impregnated have yielded milk in a moderate quantity, while in very exceptional instances the flow has been considerable; but, as a rule, the secretion of the lactic fluid is most abundant when the animal has produced a calf at the usual period of gestation, the calf being pure, not cross. The sex of the calf has been supposed to influence the amount of the secretion: with a bull-calf, the quantity, it is generally believed, is greatest.

The cow may be kept in milk up to within a month of the period of calving, but should be allowed to get gradually dry from six to twelve weeks previous to the expected period of parturition. In dairies where cows are kept for supplying towns with milk, it is customary to fatten the cows. The animals are supplied with highly nutritious food, the secretion of milk being kept up by every means, till the falling-off is so considerable, as to render it more profitable to supply her place with another cow about to produce, or one which has recently produced. The cow is sometimes dried in the dairy, and fattened off; the more common practice, however, where the food is purchased, is to part with the cow in a half-fattened state. In dairies where the produce is manufactured into butter or cheese, the practice is to keep the same cows, parting with them only when, from age or other causes, they are unsuitable for producing the average maximum of milk. On breeding-farms where the calf follows the dam, the cows are usually sold at six or seven years, their place being supplied by young heifers.

Calving.—When in a state of health, no difficulty will occur at the parturition. The cow should be kept quiet, and no assistance given except in difficult cases. A shepherd, or one familiar with stock, may assist, particularly if there is a false or wrong presentation; but the more prudent course in difficult cases is to summon the veterinary surgeon. After parturition, the calf should be removed, rubbed, and partially covered with straw. Some prefer to place the calf before the cow, sprinkling salt over the calf. Most dairy-maids also throw a portion over the loins of the cow! The calf is removed after it has been gone over by the tongue of the cow, and is either placed in a house away from the byre, or it is tied up behind the cow in the byre. The suckling of the calf is gradually becoming less practised, and is now confined principally to such mountain breeds as the West Highland, or to the more highly improved breeds, the Short-horn and Hereford. Short-horn breeders sometimes provide a nurse, drying the cow after parturition. With heifers, this practice improves the size, condition, and general symmetry. With cows, the secretion of milk is frequently impaired from the state of obesity in which the animal is kept. Such cows, after parturition, should receive one pound Epsom salts, with one ounce of nitrate of potash, and two drachms of ginger, and the flow of milk encouraged. Cows kept for milk should receive no medicine, an occasional handful of salt excepted. This, given in warm drinks, will tend to induce thirst; to allay which, more water, with the chill taken off, and containing a portion of the water in which barley has been boiled, should be given. The allowance of food should be restricted to two handfuls of boiled barley daily, with hay or green food. No roots, meal, or cake should be allowed for the first three days; after which, if no unfavourable symptoms appear, the quantity of food should be gradually increased, and cake allowed; care being taken that the cow does not partake of cold water for some time after calving.

Calves not suckled should receive warm milk twice, still better, three times in the twenty-four hours. The

* In Dodd's *Food of London*, published by Longmans, will be found much curious information on this interesting subject.

quantity at one time, for the first two weeks, should not exceed three pints. Afterwards, the quantity of milk should be gradually increased. In fattening calves for veal, there is little danger from giving as much milk by the third week as the calf will take. Some feeders give eggs in addition to milk—two or more eggs daily. The shell is broken, and the egg is placed over the root of the tongue. When the allowance of milk is what the calf will drink, chalk should be added occasionally—one quarter to half a pound weight; this assists digestion. The calf intended for slaughtering should be kept dark, confined in little space, and receive no other food than milk. Whiteness of flesh indicates that the feeding has been only milk. The common practice of slaughtering calves a few days, and sometimes only hours old, should be legally suppressed. In France, where upwards of two millions of calves are annually slaughtered, calves cannot be exposed in the metropolitan markets till they are five weeks old. Inspectors of the markets and of the abattoirs render the slaughtering of calves under the legalised age all but impossible. Calves advance in weight about two pounds a day, when they receive seven to ten pounds of milk. Thus a calf weighing at birth 85 to 100 or more pounds, will in five weeks almost double its weight. For the first eight days, the weight rather decreases. Five-eighths to six-eighths of the live weight is considered the dead weight. In this country, veal is not much prized; in France, and some other continental states, from the attention bestowed upon feeding the calves, veal is regarded as a luxury, occupying nearly the same place as lamb in this country.

Calves to be reared, should have abundance of milk for the first four weeks, and that the milk of a cow newly calved. After four weeks, linseed or linseed-cake gruel should be allowed—not mixed with the milk, but given at a different time; the one diet of milk, the other of gruel. Hay or grass may be hung up within reach, and cake finely broken placed in a trough before the calf. As the animal takes to the gruel, cake, and grass, the milk should be gradually withdrawn, care being taken so to maintain condition, that the plumpness of the well-nursed calf is not lost. After the calf eats grass freely, it may, along with others, be turned out to a small paddock, but housed during the night. If a male, and not intended to be reared as a bull, it may be castrated when one month old, a west wind and a mild temperature being chosen for operating. Heifers are now seldom spayed; the operation is difficult, and, except the person is expert, spaying should not be attempted.

Modes of Feeding.

The cow, after recovery from calving, requires an abundance of food, to keep up the secretion of milk. The feeding should be regular, from morning to night, and water must be offered at proper intervals, if the animal has not the full liberty of drinking out of a pond or running stream.

Regarding the nature of the food of cows, although soiling, or artificial feeding in the house, is at all times economical, there can be no doubt that the best milk, butter, and cheese are produced by cows fed on natural pasture. Permanent pastures are to be preferred. Those lands having a damp and saline bottom produce the most suitable food. On enclosed farms, it is the custom of many to keep their cows out both night and day from May till the end of October, so long as a full bite can be obtained; while others bring them into the house twice a day to be milked. In moorland and unenclosed districts, they are put under the charge of a herd through the day, and are brought into the byres during the night. In either case, exposure to wet and cold, or to extreme heats, should be guarded against.

Soiling, or feeding entirely in the house or court-yard, is seldom practised. Partial soiling is occasionally resorted to, by serving out a considerable quantity of rich green food to the dairy-stock in their stalls at night and during the heat of the day. This mode of feeding is more especially followed when the pastures begin to fail; the second crops of clover and first crop of tares, cabbages, and other farm-produce, are all given to the cows in the house at this period. In the best managed dairies in Scotland, when the cows are taken in for the winter, they are never put out to the fields until spring, when the grass has risen so much as to afford a full bite. In the moorland districts, however, they are put out to the fields for some hours every day when the weather will permit. In these districts, the winter food is marsh-meadow hay, occasionally straw, with turnips, boiled chaff, and other refuse from the barn. In the best dairy-districts in England, the cows are fed principally on hay during the winter and spring months. In the vale of Gloucester, &c., the number of acres required for hay equals the number depastured, about 150 stones of hay being produced on the acre. A small portion of roots, turnip, mangold, white carrot, is allowed by most dairy-farmers. Cows in milk have the turnips sparingly supplied. When they are milked, a small piece of nitrate of potash is placed in the milk-pail; the milk as it flows from the udder dissolves the nitrate—this removes almost wholly all traces of the peculiar taste of the turnip.

Where convenient, the cows should be changed from one field to another. Eight days is the longest period they should remain in the same field. Some dairy-farmers prefer to shift the cows daily, grazing in one field during the day, the other during the night, the cows returning to the byres to be milked morning and evening. The study at all seasons when the cows are in milk should be, to provide an abundance of food, succulent, varied, and nutritious. The Scottish adage conveys a great deal of truth—'What gangs in at the *mou* (mouth) maks the guid milk *coo* (cow).'

Milking.

Cows are milked twice or thrice a day, according to circumstances. If twice, morning and night; if thrice, morning, noon, and night. They should not go too long unmilked, for, independently of the uneasiness to the poor animal, it acts injuriously on the secretion of milk.

The act of milking is one that requires skill; for if not carefully and properly done, the quantity of the milk will be diminished. To insure a continuance of the flow of milk, it should, therefore, be thoroughly drawn from the cows until not a drop more can be obtained. Cows should be soothed by mild usage, especially when young; for, to a person whom they dislike, they never give their milk freely. The teats may be washed clean before milking; and when tender, they ought to be fomented with warm water. If there are any sores, lard should be rubbed on the palm of the hand, and afterwards on the teats. The milking and management of the cow should be intrusted only to servants of character. In the majority of the counties of England, it is a common practice to employ men to milk the cows, an operation which seems better fitted for women, who are likely to do the work in a more gentle and cleanly manner. In Scotland, the office is exclusively confined to women; so capriciously do customs seem to vary.

Milk.

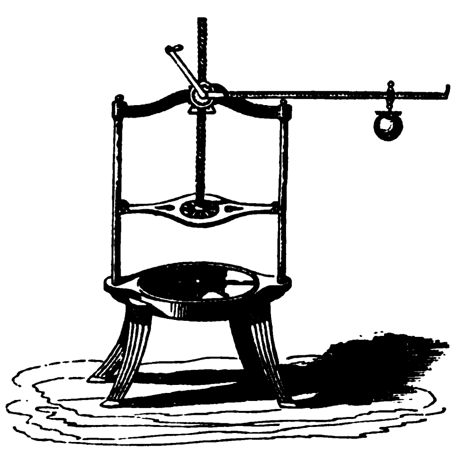
Milk is ascertained to be composed of numerous elements, being in composition similar to blood and flesh, the proportion of water being greater. The milk of the cow seldom contains more than 13 per cent. of solids, the average being about 12 per cent. The character of the food, the breed of cattle, the length of time since the cow has calved, with several other influencing causes, determine in part the relative proportions of the various elements. When taken from the cow, milk should be removed to the dairy or milk-house,

and after being sieved, placed in shallow pans, to throw up the butteraceous matter termed cream, which, like all fatty substances, being lightest, floats on the top.

THE DAIRY.

A well-arranged dairy should consist of separate apartments, in which the various operations can be carried on—the milk-room, the cheese-room, the machine-room, and a boiler-house in which the various utensils can be washed. If completely isolated from other buildings, with the milk and cheese room facing the north, these apartments will be more easily kept cool. A covered verandah before the door, under which the washed utensils may be placed to dry, will be found useful. The milk-room should be cool, airy, dry, and free from vermin of all kinds. To prevent the intrusion of flies, the windows or ventilators ought to be covered with a fine wire-gauze. The floor should be laid with pavement, formed of sandstone, limestone, or slate; smooth glazed tiles are suitable, and where used, they should also be placed around the lower part of the walls. The benches on which the milk-pans are to be placed are made of stone or slate, and about thirty inches broad. The ceiling should be at least eight feet from the floor, and finished in every respect like that of an ordinary dwelling-house. A slate-roof is preferable to one of tile, as it tends to keep the temperature more equable. Cleanliness is most essential in dairy-management.

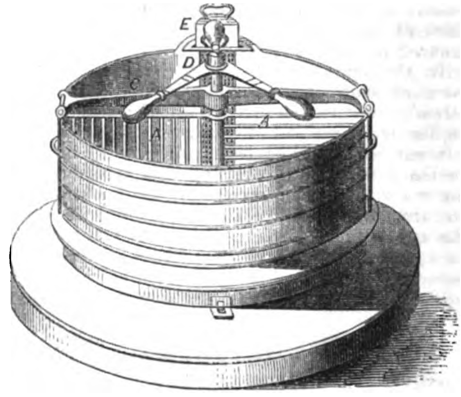
The utensils of a dairy are numerous. The principal are milk-pails, shallow coolers for holding the milk, sieves for straining it through after it is taken from the cow, dishes for skimming the cream, churns for making the butter, scales, weights, &c. For making cheese, there are likewise required vats, tubs, curd-breakers, and presses; and various other articles. Vessels for the milk-room are composed of different materials, wood being generally used—wood lined with tin, cast iron, enamelled earthenware, glass, and zinc. In Holland, the milk-dishes are very commonly made of brass. Zinc, and even lead-glazed earthenware vessels are objected to, on account of the action, or supposed action, of the acid of the milk on these materials producing an active poison. Glass is a good material in which to place the milk; and by using the iron vessels lined with it by a new and durable process (manufactured by the Birmingham Malleable Iron Tube Company), the only objection—its brittleness—is at once obviated.



Messrs Richmond and Chandler's Cheese-press.

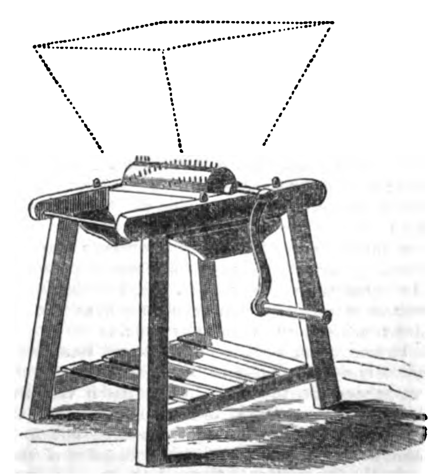
Cheese-presses are of various kinds and weights. Granite is preferred. Presses formerly consisted of a stone weight placed upon the sinker, which was raised and depressed either by a block and tackle or a screw. The above figure represents an improved form of cheese-press, manufactured by Messrs Richmond and Chandler, Salford.

A patent cheese-making apparatus coming into use in well-managed dairies is represented in the following figure. The inventor is Mr Keevil of Lacock, near



Cheese-making Apparatus.

Chippenham. The milk is placed in the apparatus, and curded in the usual manner. When the curd is ready to be broken up, the knives, A, A—one set of which is placed horizontally, the other vertically—are turned gently round by the small levered handle shewn in the drawing. When the curd is cut into sufficiently small pieces, the beam, C, is taken off, the knives removed, and the curd is left to settle. When the whey is ready to be drawn off, the curd is removed with a skimmer from the face of the filter, D; the plug, E, is then drawn out, and a tap, placed at the bottom of the filter, is turned on, and the whey allowed to run off. In the sketch, the plug, E, is shewn partly drawn up; when commencing to use the apparatus, it is of course pushed quite down. When the whey has run off, so as to leave the body of the curd visible, a tub-cloth is placed over it, and on this a *pressing-plate*. A beam provided with a nut, in which a vertical screw works, is then fixed in a position corresponding to C. The pressure of the screw, which is turned by a handle similar to that shewn in the



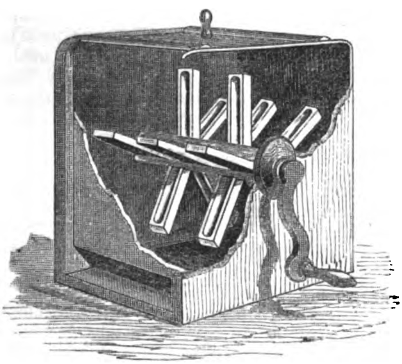
Curd-cutter.

sketch, is transmitted to the pressing-plate through the medium of cross arms or bearers, which are placed over

the pressing-plate before the beam and vertical screw are fixed. The pressure is applied gently at first, till the whey ceases running from the filter-tap. The pressing-plate and arms are then removed, the curd cut and packed in a peculiar manner, and again subjected to pressure. This is repeated till the curd is dry. An apparatus measuring 2 feet 4 inches in diameter, and 1 foot 7 inches deep, holds the curd of forty-two gallons of milk, and is capable of making cheese from ten cows once a day, or from twenty cows twice a day. The price of such an apparatus is £16.

In the figure near the bottom of last column, a form of *curd-cutter* much used in the dairies of Cheshire is represented; it is manufactured by Cornes of Nantwich, Cheshire, price £2.

Great improvements have been recently introduced in the mechanism of *churns*. The *plunge* or *barrel* churn is rarely used except in cases where it can be worked by power. The *box*-churn with vertical dashers is now much used. The annexed figure



Anthony's American Atmospheric Churn.

represents a modification of the box-churn known as Anthony's American Atmospheric Churn. This has a high reputation.

Butter

that is made from milk as obtained from the cow, contains more caseine than butter made from the cream. The greater portion of the butter produced in England is from the cream, which is collected in about thirty-six to forty-eight hours after the milk is placed in coolers, the depth of the milk being regulated to about three to four inches. The cream, as it is gathered and allowed to stand for a time, acquires acidity, the sugar of milk undergoing a chemical change. The butter is produced by churning. The temperature of the milk when put into the churn, the form of the churn, and the speed at which it is moved, all influence the period required to separate the butter from the milk; which milk, after the butter is collected, is termed sour-milk, butter-milk, &c. The time required before the cream of the milk, or the milk drawn from the cow, should be put into the churn, differs materially during warm weather; two days may be sufficient, especially if sweet butter is desired. A longer period than two days, however, is generally observed, as the quantity of the butter is an important element.

The length of time the milk should stand before the cream is skimmed, should be regulated by the weather; during summer, thirty-six hours; but if very hot, with much electricity in the atmosphere, twenty-four hours are sufficient. In winter, forty-eight hours, or even longer, may be necessary to the collection of the whole cream on the surface. To produce superior butter, the cream should be early collected, and only once. Churning should proceed within forty-eight hours after the cream is gathered. The temperature should be regulated to about 51 degrees Fahrenheit in summer, and 55 degrees Fahrenheit in winter; the agent employed, cold or hot water. The temperature at which butter can be produced by agitating the milk, has been ascertained to range from 50 to 80 degrees Fahrenheit. Some colouring matter is usually added to the milk previous to churning. Saffron, anotto, juice of the carrot, are used. All colouring matter should be avoided; but the public opinion as to the colour of rich butter, guides practice. In Holland, the butter produced in winter is white. The colour obtained from the cows depasturing on old rich pastures, is a colour lighter than the greater portion of the butter exposed for sale—salt, powdered, or fresh. Churning at a low temperature retains a portion of the colouring matter, which otherwise would pass into the butter-milk.

The best quality of butter is obtained at a temperature of 51 degrees, according to experiments performed by Mr Poole; and the greatest quantity at a temperature of 56 degrees. During the process of churning, the agitation will increase the heat about 5 degrees.

In some of the dairies in the neighbourhood of Edinburgh, and in all those near Glasgow, as indeed in Scotland and Ireland generally, the butter is made by churning the cream and the milk together. This is done in order to obtain the butter-milk, the demand for which is generally great. When the milk and cream are to be churned together, the milk is kept in the coolers for from twelve to twenty-four hours, and then poured into a milk-tub. It remains here until required for churning, and will, during this time, have partially coagulated. If a certain quantity of milk is put into the milk-tub, and has coagulated, it should be churned, or too much fermentation may be the consequence. The milk is not churned till it has become slightly acid. When once coagulation has taken place, it should be churned as early as convenient. If the milk has not fermented before churning, the butter-milk will keep for a much longer time, and will have a more agreeable taste. When the milk has fermented before being churned, the butter-milk will never be so good, nor will it keep for such a length of time.

The operation of churning, whether it be of cream alone, or cream and milk, is performed in the same manner. The milk requires more time than cream to complete the process, from two to three hours being sometimes necessary, while cream alone may be effectually churned in one-half to one hour. It is necessary that the operation should be slow in warm weather; for if done too hastily, the butter will be soft and white. In winter, the operation of churning should be done as quickly as possible, the action being regular; and the churn should be warmed, to raise the temperature of the milk or cream. The air which is generated in the churn should be allowed to escape, or it will impede the process by the froth which it creates. After the butter is formed, it should remain in the churn to cool for one hour in summer.

After the churning is performed, the butter should be washed with cold spring-water, with a little salt added, the water being changed two or three times, to extract all the milk which may be lodging in the mass. It is said by some, that the butter retains its sweetness much longer when no water is used, the milk being expelled by the pressure of the hands when working the butter. Others affirm that the washing improves the flavour. If butter is intended for salting, it is important to free it of the milk by the use of the hand or butter-platters. After the milk has been extracted, if the butter is to be salted, it should be mixed with the finest salt, in the proportion of ten ounces to the stone of fourteen pounds, more or less, according to the time the butter is to be preserved. The butter and salt should be well mixed together with the hand. In Ireland it is customary to add a little saltpetre. A mixture of one part sugar, one part nitre, and two

parts of the best salt, finely powdered together, has been highly recommended.

In salting, the butter should never be put into the firkins in layers; but the surface should be left every day rough and broken, so as to unite better with that of the succeeding churning. The quality is preserved by covering it from the air with a clean linen cloth dipped in pickle, and finally, by placing it in a cool situation. The air should be excluded by a pickle of salt and water, with a covering of fine linen, over which the top should be pressed down.

The annual import of butter into the United Kingdom for home-consumption, is about fifty-five millions of pounds' weight.

Butter-milk.

This is the liquid which remains after removing the butter. If milk has been employed for churning, the butter-milk is inferior to that from cream. Good butter-milk is exceedingly wholesome and nutritious. In Ireland, it is largely used at meals with potatoes; in Scotland, it is more frequently partaken of with oatmeal porridge. For this purpose, large quantities are brought to Glasgow, Edinburgh, and other towns, from the adjoining rural districts. In England, the butter-milk of farmers is usually employed in feeding pigs. In some districts, skim-milk is also given to pigs. Latterly, butter-milk has been used in conjunction with carbonate of soda in the preparation of a light and wholesome household bread. In the west of Scotland, a kind of cheese is prepared from the butter-milk.

Cheese.

Cheese may be made from cream alone, or from the whole milk; also from skim-milk and from butter-milk; the process consists in separating the serum from the other materials. This is effected by curdling the cream or milk by the infusion of an acid, the refuse being the serum or whey, which is of little value. No acidulous substance is found so suitable for curdling milk as *rennet*, which is formed of the stomach of a calf that has been fed on milk. Some persons preserve the maws or stomach-bags of calves with the curd contained in them; others employ the stomach-bags alone, putting a few handfuls of salt into and around them. They are then rolled up, and hung in a warm place to dry, and are kept for some time before they are used. The stomach is not made use of in Gloucestershire until it is a twelvemonth old; for, if used before this, it is said to swell the cheese, making it full of *eyes* or holes. The usual way of preparing the rennet in England is to add to every six skins or stomachs two gallons of brine, and two lemons, which take away any unpleasant taste, and give the rennet an agreeable flavour. A large quantity is made at a time; and it is never used until it has stood at least two months. In Cheshire the rennet is prepared every morning; a portion of the vel or stomach is cut off, and put into hot water; after it remains some time, the liquid is added to the milk. A portion equal in size to a half-penny, will curd the milk of thirty to forty cows. Rennet so obtained does not impart any disagreeable taste to the cheese. Rennet prepared by the more common method, generally gives an unpleasant taste. Almost every dairy county has its own particular method of steeping and salting the maws and preparing the rennet.

Whey.

Whey, or the thin watery serum of milk, is of a pale-greenish hue, and forms an agreeable beverage. Some dairy-farmers in England are in the habit of extracting a little butter from it. In Scotland, whey is used in making oatmeal porridge; and a saving of nearly one-third of meal is effected when the porridge is made of whey instead of water. By boiling, float-whey, as it is called, is obtained, which, when mixed with a little sweet milk, is thought little inferior to curd. Whey is valuable in feeding swine. Sugar is prepared from whey. The production of crystallised milk-sugar is chiefly confined to Switzerland. It is sold in thick crystalline crusts; colour, yellow and yellow-brown. The production is limited, and does not compete with sugar from the cane or beet-root.

We now propose to give brief descriptions of the process of cheese-making in the most celebrated districts in this country—Cheshire, Gloucestershire, and the west of Scotland.

Cheshire Cheese.—It has been remarked, that although good imitations of the cheese made in the English counties have been produced elsewhere, yet cheese possessing the true Cheshire flavour are exceptional. This is attributed to the abundance of saline particles in the soil. Cheshire is almost entirely a dairy county. In making the cheese, the practice followed is to set the evening's milk apart till the following morning, when the cream is skimmed off, and two or three gallons of the skimmed-milk is put into a vessel, which is immediately placed in hot water, and rendered scalding hot. Half of the milk thus heated is poured upon the night's milk, and the other half mixed with the cream. The morning's milk is added to that of the previous evening, and the rennet and colouring being then put into the tub, the whole is well stirred, and a wooden cover put over the tub.

When the curd is formed, it is cut with the cheese-knife, making the incisions about an inch distant from each other; the whey is removed as it collects on the surface. The curd is then broken by the dairy-woman, until every part of it is made as small as possible, about forty minutes being generally spent in this process, when the curd is left about half an hour to subside, covered over with a cloth. After this, the curd is put in a favourable position in the tub to drain; after which it is cut into pieces, and pressed both with the hand and a weight, so long as the whey continues to flow.

The curd is now broken very small, and salted. As soon as the curd adheres together, a weight is put upon it, and several iron skewers are stuck through it by holes in the sides of the vat. These holes are made in order to allow any whey to escape. The curd is afterwards broken as small as possible. The pressing and skewering are again repeated. When no more whey can be extracted, the curd is turned in the vat, and rinsed in warm whey. The cheese is next put into the press, skewered with strong wires, eighteen or twenty inches long, and sharp at the points. The vat is furnished with holes on the sides to receive the skewers. After being about half an hour in the press, the cheese is turned several times, and each time supplied with a dry cloth. This instrument is continued for forty-eight hours, and then the cheese is put mid-deep into salt, its top covered with salt, where it remains for three days, its position being reversed each day. When taken out of the vat, it is put into a wooden hoop or girth of the same breadth as the thickness of the cheese, and is placed on the salting-bench, where it stands about eight days, being well salted during that time. It is then washed and dried, and rubbed with sweet butter.

These cheeses vary in size, being in some dairies nearly 140 pounds in weight. The quantity of salt made use of during the process is uncertain.

The double Gloucester cheese, which is held in such high repute, is almost wholly made in the vale of Berkeley in Gloucestershire. Its excellence is said to depend much upon the quality of the land, and the great attention that is paid to the management of the dairies. It is usually made in the months of May, June, and July, and the process of manufacturing is as follows:

When the curd—which is seldom prepared from artificially heated milk, but, if possible, from the milk

as it is drawn from the cow, and when it has fallen to about 85 degrees—is considered firm enough for breaking, it is cut gently and slowly into squares of about an inch; standing, to allow the whey to gather, it is again cut. After the whey is removed, the curd is pressed down with the hand into vats, covered with large cheese-cloths of fine canvas, and placed in the press for half an hour. It is then put into a mill, which crumbles it to small pieces, thus saving the labour of squeezing and rubbing with the hands. A cheese-cloth is spread over the vat, and a little hot water thrown over the cloth, which has a tendency to harden the outside of the cheese, and prevent it from cracking. The curd is next turned out of the vat into the cloth, and the inside of the vat being washed in whey, the inverted curd with the cloth is returned to the vat, and is put into the press for two hours, when it is taken out, and dry cloths applied through the course of the day. It is then replaced in the press until salted, which is generally performed about twenty-four hours after it is pressed. In salting, the cheese is rubbed with finely powdered salt; and this is thought to make the cheese smoother and more solid than when the salting process is performed upon the curd. The cheese is after this returned to the vat, and put under the press, in which more than one are placed, the newest one at the bottom, and the oldest on the top. The salting is repeated three times, twenty-four hours being allowed to intervene between each; and the cheese is finally taken from the press to the cheese-room in the course of five days. In the cheese-room, it is turned over every day for a month, when it is cleaned of all scurf, and rubbed over with a woollen cloth, dipped in a paint made of Indian red or Spanish brown and small-beer. As soon as the paint is dry, the cheese is rubbed once a week with a cloth. One pound of anotto is sufficient to colour half a ton of cheese.

The single Gloucester is half skim-milk cheese; 'the double Gloucester or *best making* cheese, is manufactured from the pure or unskimmed milk; although it is not unusual in a large dairy to set aside sufficient milk to afford cream and butter enough for the family, and afterwards to add it to the next day's milking. These are sometimes called *coward* cheeses; they are either thin, weighing about sixteen pounds per cheese, or thick, averaging from thirty to forty pounds. The best single Gloucester is either the *two-meal cheese*, made of equal portions of unskimmed and skimmed milk, or sometimes two portions of skimmed-milk and one part of pure or *coward* milk.'

Stilton cheese is made by putting the night's cream, without any portion of skimmed-milk, into the next morning's milk; but those who wish to make it very fine, add still more cream; and thus its richness depends upon the quantity of cream made use of. Butter is also said sometimes to be used in its manufacture. The rennet is then added without any colouring; and when the curd has formed, it is taken out without being broken, and put whole into a sieve or drainer. In the drainer it is pressed with weights until all the whey is extracted, and when dry, put into a hooped chessel. The outer coat being salted, it is then put into the press, and when sufficiently firm, it is taken out of the chessel, and bound tightly in a cloth. This cloth is changed every day until the cheese is quite dry, when it is removed; and the cheese requires no further care except occasional brushing and turning. The Stilton cheeses, although small—not weighing more than twelve pounds—require two years to bring them to full maturity.

Dunlop cheese, although nowhere so well made as in the parish in Ayrshire from which it derives its name, is now manufactured in the dairy districts of Scotland generally. The cheeses are made of various sizes—from a quarter to half a hundredweight; and the process of making them is as follows. Sometimes the entire milk is used, but generally the cream is removed from the evening's milking. When so many cows are kept upon a farm that a cheese can be made every time they are milked, the milk is passed through a sieve into the vat, and formed into curd by the rennet. But when the cows are not so numerous as to afford milk sufficient to form a cheese at each milking, it is put into the coolers about six or eight inches deep. At the next milking, the cream is skimmed off, and without being heated, the milk is put into the curd-vat along with that just drawn from the cows. The milk is then raised to a temperature about blood-heat, or in summer to 90 degrees, and in spring 95 degrees. If coagulated much warmer, the curd becomes too adhesive; and some of the butteraceous matter is lost in the whey.

After the adding of the rennet, and the removal of the whey, the curd is cut, salted, and prepared for the vat —thirteen ounces of salt to twenty-four pounds being sufficient. A clean cheese-cloth, rinsed in warm water and wrung out, being then placed in the chessel, the curd is put in, and is pressed for about one hour, taken out and turned, and afterwards placed in the press. Some have shortened the process of pressing by placing the cheese, when it comes from the press for the first time, into water heated to about 95 or 100 degrees, where it remains till the water becomes milk-warm. The cheese is then dried well, and again placed under the press.

When ultimately taken from the press, the cheeses are generally exposed for about a week to a considerable degree of drought, turned over every twenty-four hours, and rubbed with a dry cloth. They are then removed to the store-room, which should be in a cool exposure, between damp and dry, without a current of air. The cheese is sometimes coloured with an infusion of anotto or saffron, but the practice is not general.

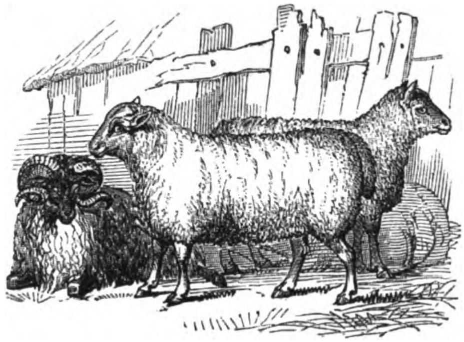
In Ayrshire and in some other counties, imitation cheeses of the most esteemed kinds, Stilton, Cheshire, and Gloucester, are made. A few dairies now produce cheese so closely resembling the best kinds of English in form, colour, and aroma, as to pass with the consuming public as English cheese. A deputation of Ayrshire farmers visited some of the best dairy-farms in England. Since then, more attention is being yearly bestowed on the manufacturing of cheese similar to the English kinds. English dairymaids, where introduced, have found no difficulty in producing superior cheese in the west of Scotland.

Parmesan cheese is manufactured in that part of Italy which lies between Cremona and Lodi, comprising the richest portion of the Milanese territory. The cows are kept in the house nearly all the year round, and fed in summer with cut grass from the rich irrigated meadows of the country. Some of the cheeses are so large as to contain nearly 180 pounds; and the milk of 100 cows is required to produce one of this size. This cheese is made from the milk of the evening, which is skimmed in the morning and at noon, and the milk of the morning, which is also skimmed at noon. The milk is heated to about 120 degrees. The rennet is then added.

Swiss Cheese.—The finest cheese made in Switzerland is that of Gruyere, in the canton of Fribourg. It is rich in quality, and generally flavoured with a powdered dry herb, the *Melilotus officinalis*. The cheeses weigh from forty to sixty pounds each, and are exported in large quantities.

Dutch cheeses are sold under various names in this country—Gouda, &c. Holland exports annually about 30 millions of pounds of cheese, the greater portion coming to England.

The annual import of cheese into the United Kingdom, for home consumption, is about forty-five millions of pounds.



Black-faced—Leicester—South-down.

THE SHEEP—GOAT—ALPACA.

IN the *Ruminant* order of the Mammalia, a distinguished place is given to the sheep, the flesh and wool of which have been recognised as alike of the greatest use to man from the earliest ages. In our own country, within the last half-century, the different breeds have been improved by the growing intelligence, skill, and industry of the farmers; and their management has, under high patronage, been brought to a degree of perfection perhaps nowhere else attained. It may be added that, as the sciences of anatomy, physiology, botany, and chemistry are every year throwing new light on those laws of nature which regulate the structure, health, nutrition, and reproduction of the Animal Kingdom, we may entertain the hope of still further improvement in this department of rural economy.

BREEDS OR VARIETIES OF THE SHEEP.

The numerous varieties of sheep that now exist in different parts of the globe, have all been reduced by Cuvier into four distinct species:—1. *Ovis Ammon*—the Argali. This species is remarkable for its soft reddish hair, a short tail, and a mane under its neck. It inhabits the rocky districts of Barbary and the more elevated parts of Egypt. 2. *Ovis tragelaphus*—the bearded sheep of Africa. 3. *Ovis musmon*—the Musmon of Southern Europe. 4. *Ovis montana*—the Mouflon of America; but this species, which inhabits the Rocky Mountains of North America, is now believed to be identical with the Argali, which frequents the mountains of Central Asia, and the higher plains of Siberia northward to Kamtschatka. This leaves only three distinct species of wild sheep as yet discovered.

It is still a point in dispute from which of these races our domestic sheep have been derived; nor is the question of great practical importance, though its solution is very desirable in a physiological point of view. Whether the wild races may be regarded as of one species, as some naturalists contend, or of different species according to others, the best judges are next to unanimous that the domestic races of this country are of one species; and what are called different breeds, are nothing more than varieties, the result of different culture, food, and climate. The influence of these conditions in diversifying the character and condition of sheep, will be adverted to under their proper heads.

The following may be regarded as the principal breeds reared in this country:

1. *The Shetland sheep*, inhabiting those islands from which they derive their name, and extending to the Faröe Islands and the Hebrides. In general, they have no horns. The finest fabrics are made of their wool, which resembles a fine fur. This wool is mixed with a species of coarse hair, which forms a covering for the animal when the fleece proper falls off. A similar variety is known to inhabit the most northerly parts of Europe, from which it is supposed the fine-wooled sheep of our northern islands and Highlands have been derived. They are hardy in constitution, and well adapted to the soil and scanty pastures on which they are reared, but would ill repay their cultivation in Lowland districts.

2. *The Dun-woolled breed*, the colour of which is not confined to the wool, but extends to the face and legs. They seem at one time to have been cultivated very extensively, and remnants of them still exist in Scotland, Wales, and the Isle of Man.

3. *The Black-faced heath breed*, which, being the most hardy and active of all our sheep, are the proper inhabitants of every country abounding in elevated heathy mountains. They have spiral horns, their legs and faces are black, with a short, firm, and compact body; their wool is coarse, weighing from three to four pounds per fleece; but the improved breed, which is brocked in the face and legs, yields a finer and a whiter wool. They fatten readily on good pastures, and yield the most delicious mutton, weighing from ten to sixteen pounds per quarter. They still exist in considerable numbers in the more elevated mountains of Yorkshire, Cumberland, Westmoreland, Argyleshire, and the central Highlands of Scotland.

4. *The Moorland sheep of Devonshire*—sometimes termed the Exmoor and Dartmoor, from the different districts of Devonshire in which they are reared—have horns, with legs and faces white, wool long, with a hardy constitution, and are said to be well adapted to the wet lands which they occupy. Their wool weighs about four pounds the fleece; but they are rather small, and in some respects ill formed.

5. *The Cheviot breed*, deriving their name from the Cheviot mountains, in which they are said to be indigenous, are longer and heavier than the black-faced. Their wool is fine; a medium fleece weighs about three

pounds; a carcass, when fat, weighs from twelve to eighteen pounds per quarter. Their faces are white; their legs are long, clean, and small boned, and clad with wool to the hough. Their only defect of form is a want of depth in the chest; yet, with this exception, their size, general shape, hardy constitution, and fine wool, are a combination of qualities in which, as a breed for mountain pasturage, they are yet unrivalled in this country.

6. *The Horned varieties of fine-woolled sheep of Norfolk, Wiltshire, and Dorset.*—The members of this breed have short wool, in which they differ from the black-faced sheep and moorland sheep of Devonshire, and from the Cheviot, in having large spiral horns. They are not much lighter than the Cheviots, but they are ill-formed, and thin, flat in the ribs, and slow feeders; a medium fleece weighs about two pounds. It is believed that the South-down will eventually displace them. The Wiltshire sheep are still heavier than those of Norfolk, being the largest of our fine-woolled sheep; they are said to thrive well in the downs of Wiltshire, but are also giving ground to the South-downs. The Dorset sheep have horns, white faces and legs; their three-year-old wethers weigh from sixteen to twenty pounds per quarter; their wool is less fine, but heavier than that of Wiltshire, weighing from three to four pounds the fleece. One of the peculiar advantages of this breed is, the ewes admit the ram at so early a period that they generally have lambs in the months of September and October—a stock which finds a ready market in large towns for winter consumption.

7. *The Ryeland breed*, deriving their name from a southern district in Hertfordshire, which at one time was regarded as incapable of growing anything but rye. The members of this variety are white-faced, and without horns; their general form is tolerable; they fall short of the improved breeds, in being more flat in the ribs, and less level in the back; their wool is fine, weighing from one and a half to two pounds; their mutton is delicate; they arrive soon at maturity, and fatten easily, and weigh from twelve to sixteen pounds per quarter: this breed has been crossed by the Spanish Merino. The offspring of this cross were at one time in high fame in England, under the name of the Anglo-Merino; and though their wool is said to have been of a fine quality, the breed has for long declined in popular favour.

8. *The South-down breed.*—The members of this section have no horns; their legs and faces gray. They have fine wool, which is from two to three inches in length, and weighs from two and a half to three pounds per fleece; they are slightly deficient in depth and breadth of the chest, but their mutton is excellent, and highly flavoured; they are kindly feeders, and when fat, their average weight may be stated at from fifteen to eighteen pounds per quarter. They have, from time immemorial, been reared upon the chalky soils of Sussex, but are now widely extended, and thrive excellently not only on the chalk-downs and light soils of England, but on the sheltered lawns of Scotland. In a note to the author from Lord Pitmilly, near St Andrews, are the following facts: 'I generally keep about a score of South-down ewes for early lambs; they pasture in the lawn with the black-faced wethers kept for family use. The lambs dropped early in winter 1839–40 not being wanted, were sent to Edinburgh; ten of the ewes lambed again in September 1840, and again in March 1841. Some of them had twin lambs; all did well. The September lambs I sold in August 1841, when eleven months old, at 30s. apiece. I ascribe the fact of the ewes thriving so well to the dry ground, and to their being put every night, summer and winter, into a shed, and well bedded; they have no extra food, except at lambing-time, when they get a little oil-cake or sliced turnip.' The above facts are highly deserving the attention of breeders of this variety of sheep, testifying as they do to the greatest degree of fecundity of which we have yet any authentic account.

9. *The Merino breed*, which is supposed to have been originally from Africa. Marcus Columella saw a variety from that country at some of the games exhibited at Rome. He procured some of them for his own farm, crossed them with the breeds of Tarentum, and sent the offspring of this cross to Spain. In Spain, they soon rose to such perfection and celebrity, that they attracted the attention of breeders of stock in other nations, and this breed may now be found in every part of the globe. They were imported into England for the first time in 1788. The Ryeland and other fine-woolled breeds of England were crossed by Merino rams in 1792. The Merino breed of rams were cultivated with great care by George III. The sales of his majesty's stock, which commenced in the year 1804, attracted such general attention in England, that a society was formed for promoting the breed in 1811; but the high expectations which were formed of the result of this cross with native sheep were far from being realised. The quality of the wool of the native sheep was improved, but the increased value of the fleece was an inadequate compensation for defects in the character of the animals themselves, which proved less hardy than the parent stock, were slow feeders, and very defective in form.

The Merinos that have been naturalised in this country retain their natural characters, except that they become larger in the carcass, and the wool longer and heavier, than in Spain; but the Merino, as a feeding animal, is too small and ill-formed, and the mutton deficient both in quantity and quality. These points have given rise to some controversy; but in the forcible language of Professor Low: 'It is vain that some breeders still contend for the superiority of the pure Merino; the general judgment of farmers is against them, and with perfect reason.'

The Merino sheep are cultivated in Spain and Germany with a greater regard to the wool than to the weight and value of the animal; but the farmers in England think it more profitable to raise the weight and value of the mutton; and it is believed, by those well qualified to judge, that the best Merinos, under the more rigorous climate of Britain, would never yield mutton equal in quality to that of Spain. The wool of this breed is finer than that of any other sheep. In Spain, the fleece of the ram weighs eight pounds, and that of the ewe five pounds; but this wool having such a large quantity of yolk, which absorbs every kind of impurity with which it comes in contact, it loses three-fifths of its weight by being properly washed. In Australia, whither Merinos have been imported, the breed has not only improved in size and weight, but the wool produced is quite equal to the finest sorts of Europe—the result of a mild and equable climate, and not ungenerous pasture.

10. *The Devonshire Notts, Romney Marsh, Old Lincolnshire, Teeswater, and Old Leicester sheep.*—The Devonshire Notts consist of two varieties: the one is called the Dun-faced Notts, from the colour of the face; this is a coarse animal, with flat ribs and crooked back, but it yields a fleece weighing ten pounds, and when fat, weighs twenty-two pounds per quarter when only thirty months old. The second variety is called the Bampton Notts; it resembles the former in many respects, but is easier fed, yields less wool, and has the face and legs white.

The Romney Marsh breeds are very large animals, with white faces and legs, and yield a heavy fleece, the quality good of its kind. Their general structure is defective, the chest being narrow, and the extremities coarse. The result of their being crossed by the New Leicester is still a point in dispute—one party alleging, that though the quantity of wool has been lessened, and the size of the animal diminished by the cross, yet the tendency to fatten and their general form have been much improved. On the other hand, some well-informed

breeders contend, that besides the loss of the quantity and quality of the wool, the constitution of the animal is rendered less fitted to the cold and marshy pastures on which it feeds.

The Old Lincolnshire breed are large, coarse, ill-shaped, slow feeders, and yield indifferent mutton, but a fleece of very heavy long wool. The Teeswater breed were originally derived from the preceding, and pastured on the rich lands in the valley of the Tees, from which they derive their name; but Professor Low remarks, that 'it is entirely changed by crossing with the Dishly breed, and that the old unimproved race of the Tees is now scarcely to be found.' They are very large, and attain a greater weight than almost any other breed—the two-year-old wethers weighing from twenty-five to thirty pounds per quarter, and yielding a long and heavy fleece.

The Old Leicester is a variety of the coarse long-woolled breeds. On rich pastures, they feed to a great weight; but being regarded as slow feeders, their general character has either been changed by crossing, or altogether abandoned for more improved varieties.

11. *The New Leicester and Improved Teeswater breeds.*—Mr Bakewell of Dishly, in the county of Leicester, has the honour of forming this most important breed of sheep. He turned his attention to improving the form of feeding animals about the year 1755. The exact method he followed in forming his breed of sheep is not accurately known, as he is said to have observed a prudent reserve on the subject. But we now know that there is but one way of correcting the defective form of an animal—namely, by breeding for a course of years from animals of the most perfect form, till the defects are removed, and the properties sought for obtained. The great properties of the New Leicester for the farmer, are their early maturity and disposition to fatten, in which they excel all other breeds. They are less in size than several other breeds, and their wool is deemed inferior to the Cheviot; but they are now reared with great success in almost every part of England and in the colonies of Australia, whither they and the South-downs were early imported.

That class of sheep now known by the name of the Improved Teeswater, is derived from the old breed. Its improvement has been chiefly effected by crossing with the New Leicester. They are not so large as the older race, but are still the largest of our improved breeds; productive in lambs, and yield a good fleece; yet their form renders them less fitted for general cultivation than the New Leicester.

CHOICE OF BREEDS.

If the farmer has rendered himself master of the constitution and character of the different breeds of domestic sheep, already given, and with the general and peculiar character of the climate, soil, and pasturage of the locality on which he is to settle, the selection of the breed that will, upon the whole, yield him the highest profit, will not be a matter of very difficult calculation. But should an error be committed on this head in the first trial, very slight experience would enable a practical farmer to correct it, unless he belong to that class of persons—unfortunately too numerous—to whom the lessons of history and experience convey neither knowledge nor correction.

The breeds best adapted to the soil and climate of the different districts of Great Britain, are arranged by Professor Low in the following manner: 1*st*, The sheep of the mountains, lower moors, and downs; and 2*d*, The sheep of the plains. The sheep of the first class have sometimes horns, and sometimes want them. The finest of them have no horns—namely, the Cheviot and South-down. One of them, the black-faced heath breed, has coarse wool; another of them, the Moorland sheep of Devonshire, has long but not coarse wool; and all the others have short and fine wool.

Of the moorland and down breeds, as they may be called, the hardiest is the black-faced heath breed; and this property points it out as the most suitable for a high and rugged country, where artificial food cannot be procured. The breed next to this in hardy properties, but surpassing it in the weight of the individuals, is the Cheviot. Where the pasture contains a sufficiency of grasses, this breed deserves the preference over any other known to us for a mountainous country. The next breed deserving of cultivation is the South-down. This breed is suited to the chalky and sandy downs of the south of England. It is in this respect a very valuable breed, but it is unsuited to the more rough and elevated pastures to which the black-faced and Cheviot are naturally adapted.

The moorland and down breeds appear to be the most deserving of cultivation in this country. Of the larger breeds of the plains, the new Leicester is the best adapted to general cultivation, and wherever an improved system of tillage is established, this admirable breed may be introduced. The Leicester, the Cheviot, and the black-faced, have for long been regarded as the breeds best adapted for the different districts of Scotland. That these three breeds have nearly stood in the same numerical ratio to one another for some years, is a good proof that each has been placed in that locality best fitted by nature for promoting its health and productiveness. The Leicester is admirably adapted to the rich alluvial soils of our cultivated plains; the Cheviot breed is peculiarly fitted for the grassy mountains chiefly formed of the transition series of rocks; then our most elevated mountain-ranges are formed mainly of primitive rocks, and covered with coarse herbage and heath, on which none but the black-faced, the most active and hardy of our breeds, could survive.

The above arrangements have generally been acquiesced in as the best possible by the farmers of Scotland. But the claims of South-downs for the middle range of the Highland pastures in Scotland have been urged in the following terms, by an agriculturist of long experience and high standing in his profession—namely, Mr Watson of Keillor: 'Having, during the last twenty-five years, been in the management or possession of a considerable breeding-flock of South-down ewes, varying at different times from 500 to 1000 in number, and during that period having had good opportunities of drawing close comparisons betwixt that and the other breeds of mountain sheep—namely, the Cheviot and black-faced—I have come to the conclusion—and am acting upon it in my own practice—that from a pasture ranging from 500 to 1200 feet above the level of the sea, having a moderate portion of green-sward, the rest whin and heather, there can be no more profitable stock of sheep kept than a flock of South-downs of the best sort. My chief reasons for having preferred this breed are—that the South-down sheep, although naturally spirited and active, are easily controlled by a good shepherd; can go over more ground for their food than any other kind of sheep, without stopping their growth; and when tried by severe storms in winter, will brave it better than even the black-faced Highland sheep; and although reduced very low in spring, sooner pick up condition than the other short-woolled sheep. As a proof of the South-downs' tendency to fatten, when put to good keep, I may mention a fact, that while I have seldom been able to produce a fat Cheviot ewe the same season that she has reared a lamb, I never fail to make good fat of the cast South-downs off grass. Their wool is so closely matted on their backs, and about the head and neck, as to be almost impervious to rain or snow; hence so soon as the storm ceases, they appear dry and comfortable, their coat not the least disordered, and altogether free from that *drouked*—Anglicè, drenched—appearance which longer-woolled sheep exhibit even for days after a winter storm.

'In all my experience, the South-down sheep have kept

remarkably healthy. I have never seen an instance of rot in my flock; while during the last twenty years, I have been forced to clear off a lot of Cheviot and also of black-faced ewes from that incurable disease. This, however, may have been owing more to the unsoundness of the pasture from which I got them, than from any peculiarity of the animals themselves. My average loss in the South-down lot has invariably been much under that of any other sheep I have bred. They are hardy, and easily managed at lambing-time; affectionate mothers, and, on moderate keep, give a great quantity of milk; and if there is any inducement for early lambs, they will go with the ram almost as soon as the lamb is weaned. When crossed with a well-bred Leicester ram, and brought into good keep, they produce perhaps the most profitable lamb that is bred, taking wool and carcass into account. I have for the last ten years put all the ewes I could spare from pure breeding to this sort of crossing, lambing the ewes on turnips in spring, then turning them, as soon as the season would permit, to the hill-pasture—the Sidlaws—till weaning-time, when the lambs are brought to the in-field pastures, and put to turnips for the winter, on which food they are kept for about 2d. per week each, and kept on the earliest grass in spring; so that in a month or six weeks after they are clipped, they are fit for the butcher, who values this cross almost as high as the pure bred South-down. The wool is of the finest quality for combing, and fetches the highest price of any British-grown wool—generally from 2s. to 2s. 2d. per pound; and the clip in a good season will average about six pounds. At sixteen months old, I have never realised less than 40s. each, wool and mutton. In Smithfield, this cross is much sought after.

'On lands where folding is found necessary, the South-down submits to this treatment better than any other breed of sheep; such, indeed, in all cases where I have put them to the test, is their spirit and hardiness, that nothing short of ill-treatment seems to injure them. Combining these facts, I can have no hesitation in recommending a South-down flock of sheep in preference to every other, on such situations as I have now described—namely, too high to be occupied during the whole season by a flock of Leicesters, and under that level above which only the native black-faced breed can be expected to thrive.

'So far as I know, it is not yet sufficiently ascertained by experience how far a cross betwixt the South-down and Leicester may be carried, so as to keep up the activity of the former with the well-known fattening qualities of the latter. Another train of breeding through the black-faced and South-down sheep, whose habits seem so much akin, seems likely to succeed. By this cross, improvement in quality of wool would be gained, while that of the mutton would not be deteriorated.' On the other side, Professor Low remarks: 'The South-down breed is best suited to the chalky and sandy downs of the South of England. It is in this respect a very valuable breed; but it is unsuited to the more rough and elevated pastures to which the black-faced and Cheviot are adapted.'

IMPROVEMENT OF BREEDS.

The first point of essential importance to be attended to by the sheep-farmer is the selection of a breed whose size and constitutional qualities best accord with the climate and the pastures on which they are to feed. An error of any magnitude in these respects would be attended with fatal effects both on the health and productiveness of the flock, and thus ruin the finances of the farmer.

It is true that sheep can exist in almost every country, and may be said to reach nearly from the equator to the poles. They are found approaching the eternal snows and icy barriers of the arctic regions; they are found at great elevations in the Cordilleras of South America, and in the still more elevated Himalaya Mountains of Asia. Yet though sheep can be reared within an immense range of latitude and temperature, it is equally true that the climate and soil fix the limits within which our domestic breeds can be cultivated with advantage. Climatic influences wear down the rocks, and thus form the soil; hence the natural pastures of all countries.

The climate, and the condition of existence which it induces, affect, with irresistible force, the structure, health, and reproductiveness of men and animals from the equator to the poles. The laws of nature cannot be transgressed with impunity. But this condition being accurately adjusted, the next objects which the sheep-farmer ought to keep steadily in view are the quantity and quality of the mutton and the wool. Nature has perhaps forbidden that the same sheep should, in any circumstances, yield the greatest weight of the best mutton, and a fleece of the greatest value. The farmer will be able easily to determine, from the country, climate, and various other considerations, to which of these he should direct his chief attention. In England, for example, the farmer finds it more profitable to promote the weight and quality of the mutton than the wool; while the farmer in Spain, Germany, and Australia, finds it his interest to attend more to the wool than the mutton.

The properties most desirable in the sheep are—1. Size; 2. Form; 3. Early maturity; 4. Constitutional hardiness; 5. Productiveness; 6. Disposition to fatten; and 7. Lightness of offal.

1. The *size* of the sheep must be regulated by the climate, the pasture, and the steepness or levelness of the lands on which it is to feed. One rule never to be violated is, that the size of the sheep should bear some reference to the nature of the pasture; and very heavy sheep are unsuited to very elevated and precipitous mountain-ranges. On this subject, a practical question of very considerable importance is still undetermined, and that is, what is the ratio of food consumed by a large animal and one of moderate size. The result of an experiment is given by Dr Parry, where it is stated, that by breeding small sheep instead of large ones, the numbers were increased from 660 to 890 ewes and lambs, and the profit from £450 to above £724. But this experiment, and all others that have been tried, have never, in our opinion, contained all the elements necessary to determine the question with anything like philosophical accuracy.

2. The *form* of the sheep should consist of that happy combination of anatomical structure on which the health and productiveness of the animal depend; and the points of practical men must be tested by this internal anatomical structure. That eminent surgeon, Mr Cline, in his Communications to the Board of Agriculture, states: 'That the lungs of an animal are the first objects to be attended to, for on their size and soundness the health and strength of an animal principally depend; that the external indications of the size of the lungs are the form and size of the chest, and its breadth in particular; that the head should be small, as by this the birth is facilitated, and affords other advantages in feeding, and as it generally indicates that the animal is of a good breed; that the length of the neck should be in proportion to the size of the animal, that it may collect its food with ease; and that the muscles and tendons should be large, by which the animal is enabled to travel with greater facility; and the bones should be small and clean.'

We may here add a description of the best proportions of a Cheviot ram, by the late Mr Culley of Northumberland: 'His head should be fine and small; his nostrils wide and expanded; his eyes prominent, and rather bold and daring; ears thin; his collar full from the breast and shoulders, but tapering gradually all the way to where the neck and head join, which should be very fine and graceful, being perfectly free from any coarse

leather hanging down; the shoulders broad and full, which must at the same time join so easy to the collar forward, and chine backward, as to leave not the least hollow in either place; the mutton upon his arm or fore-thigh must come quite to the knee; his legs upright, with a clean fine bone, being equally clear from superfluous skin and coarse hairy wool, from the knee and hough downwards; the breast broad and well forward, which will keep his forelegs at a proper wideness; his girth or chest full and deep, and instead of a hollow behind the shoulders, that part, by some called the fore-flank, should be quite full; the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight, the quarters long and full, with the mutton quite down to the hough, which should neither stand in nor out; his twist or junction of the inside of the thighs deep, wide, and full, which, with the broad breast, will keep his four legs open and upright; the whole body covered with a thin pelt, and that with fine bright soft wool. The nearer any breed of sheep comes up to the above description, the nearer they approach towards excellence of form; and there is little doubt but if the same attention and pains were taken to improve any particular breed that has been taken with a certain variety of the Lincolnshire, the same advantages would be obtained.'

3. *Early maturity* is a property of great importance to the farmer who breeds and feeds all his own sheep for the shambles; they not only make a quicker return for their food, but yield a higher profit to the breeder than slow-feeding animals. This valuable property of early maturity can be induced by breeding, food, and treatment. The new Leicester variety possesses this property in a higher degree than any other of our domestic breeds, and they also yield a greater quantity of mutton on the same quantity of food.

4. *Constitutional hardiness*, in a rigorous climate, and in bleak and elevated mountains, in which artificial food cannot be obtained, is an indispensable quality. But a farmer will seldom make a wrong selection in circumstances so obvious.

5. *Productiveness* is a property which characterises some varieties of sheep and other animals; it may be extended by careful selection in breeding, and from food and treatment. Pets have almost invariably twin lambs. The draft ewes from the mountains of Scotland have generally twins when taken to a milder climate, and kept on superior food.

6. *Disposition to fatten* is a property of very great importance to feeders, as his sheep can be made fit for the market both in a shorter period and with a less quantity of food. None of our domestic breeds possess this quality in greater perfection than the New Leicester; this quality also may be ascertained by examining the depth and breadth of the chest, according to Sir John S. Sebright. And the great physiologist, John Hunter, found that easy corpulence was concomitant with small bones; it is also accompanied with a pliable, soft, and mellow skin.

7. *Lightness of offal.*—It is obvious that to whatever extent the weight of the offal, or uneatable portion of the carcass, can be diminished, the value of the animal is increased. The perfection of an animal is, when the dead-weight of all the eatable parts approaches the nearest to the weight of the animal when alive.

Principles of Breeding.

The fundamental and essential principles of improving any of our domestic animals by breeding, consist in a skilful selection of those males and females the union of whose qualities will remove the defects and induce the properties desired. The sheep-farmer can neither raise nor keep his flock in the highest perfection of which the climate and pasture admit, without a rigid adherence to this primary principle. It was upon this principle that Bakewell formed his celebrated breed of sheep, and it is the only principle upon which any breed can be raised to the highest perfection of which it admits. *Breeding in and in*, as it is called, has given rise to a long controversy, which our increasing knowledge of the physiology of the animal economy, and a wider induction of facts, carefully observed and accurately recorded, will speedily bring to a final close. The facts now collected from a wide surface, and attested by men skilled in the sciences of physiology and anatomy, as well as by practical breeders of livestock, establish the important fact, that breeding by too near affinities, the offspring degenerates. It is a law of nature, and applies to men and animals, and even plants. The accurate experiments of Mr Knight establish the fact, that in the vegetable as well as in the animal kingdom, the offspring of male and female plants, when not related, possess always more strength and vigour than those of near affinities. Sir John S. Sebright tried many experiments by breeding in and in with dogs, fowls, and pigeons, and found that the offspring uniformly degenerated. Sir John Sinclair relates an experiment with pigs, which he carried so far that the females almost ceased to breed; and if they did breed, the offspring was so small and delicate, that they died as soon as they were born. To breed, therefore, from the same race, but of different families, is now established as the only system that will secure the highest results in the different breeds.

Crossing is a means of improving a breed that requires many concurring circumstances to insure success. The climate and the food must accord with the size and constitution of the animal to be produced. To increase the size of sheep, without augmenting or improving their food, would be a ruinous enterprise, and in the face of all principle. The attempt to increase size by crossing with heavier rams from another country, requires also great care that the food and climate be adapted to the condition and character of the expected race; for it is in proportion as size is gained by crossing, that delicacy of constitution and liability to disease are increased. The constitutional qualities of a race of sheep will not accommodate themselves to the soil or climate of a country differing much in pasturage and temperature from that on which it has been long a native, without time, great care, skill, and attention. Were we to cross our mountain Cheviot ewes with Leicester rams, the offspring would labour under two fatal disadvantages—a constitution too delicate for the climate, and a size above the pasture. An attempt was made in Scotland some years ago to raise the quality of the wool of our mountain-sheep by crossing them with Cheviot rams, and the result, so far as then developed, was a complete failure. It is therefore dangerous to directly transplant the pure Cheviot breed to high-lying districts, the system adopted being that of crossing black-faced ewes with a Cheviot ram; by this method, a hardy Cheviot stock is at length obtained.

It is now generally admitted that the male has a higher influence on the character of the offspring than the female. This law is in beautiful accordance with that beneficent design so visible in the arrangements of nature, as it enables man to bring the domestic animals to their most profitable condition in a far shorter period than if the law had been reversed. There is another fact apparently well established, that the male, by one connection, has a higher influence on the second generation than the actual father. This shews that no important change in the character of any breed can be effected, unless the crossing is continued until the fourth or fifth generation.

Age of the Parents; its Effects on the Sex of the Offspring.—Some very interesting experiments were begun some years ago, the result of which, so far as they go, tend to establish, as a general law of nature, that the offspring of a young ram and ewe, of from four to five years old, will in general be feminine, while that of an old ram and young ewe will in general be masculine.

Could this law be practically acted upon, it would be of immense advantage to breeders of stock in every country, but particularly to breeders of stock in such a country as Australia, in which the rapid increase of the number of stock is an object of so great importance. There is an able paper on this curious subject in the first number of the *Quarterly Journal of Agriculture*, containing the results of the experiments made in France, from which the following facts and views are extracted: 'M. Charles Giron de Buzarcingues proposed at a meeting of the Agricultural Society of Severac, on the 3d of July 1826, to divide a flock of sheep into two equal parts, so that a greater number of males or females, at the choice of the proprietor, should be produced from each of them. Two of the members of the society offered their flocks to become subjects of his experiments; and the results have now been communicated, which are in accordance with the author's expectations. The first experiment was conducted in the following manner: He recommended very young rams to be put to the flock of ewes from which the proprietor wished the greater number of females in their offspring, and also, that during the season when the rams were with the ewes, they should have more abundant pasture than the others; while to the flock from which the proprietor wished to obtain male lambs chiefly, he recommended him to put strong and vigorous rams four or five years old. The following tabular view contains the result of these experiments, which are strongly in favour of the views of M. Giron:

FLOCK FOR FEMALE LAMBS.		
Age of the Mothers.	Sex of the Lambs.	
	Males.	Fem.
Two Years old,	14	26
Three Years,	16	29
Four Years, .	5	21
Total, .	35	76
Five Years and older, .	18	8
Total, .	53	84

N.B.—Three twin-births in this flock. Two rams served it, one fifteen months, the other nearly two years old.

FLOCK FOR MALE LAMBS.		
Age of the Mothers.	Sex of the Lambs.	
	Males.	Fem.
Two Years old,	7	3
Three Years,	15	14
Four Years, .	33	14
Total, .	55	31
Five Years and older, .	25	24
Total, .	80	55

N.B.—No twin-births in this flock. Two strong rams, one four, the other five years old, served it.

'The general law, as far as we are able to detect it, seems to be, that when animals are in good condition, plentifully supplied with food, and kept from breeding as fast as they might do, they are most likely to produce females; or, in other words, when a race of animals is in circumstances favourable for its increase, nature produces the greatest number of that sex which, in animals that do not pair, is most efficient for increasing the number of the race. But if they are in a bad climate, or on stinted pasture, or if they have already given birth to a numerous offspring, then nature, setting limits to the increase of the race, produces more males than females. Yet, perhaps, it may be premature to attempt to deduce any law from experiments which have not yet been sufficiently extended. M. Giron is disposed to ascribe much of the effect to the age of the ram, independent of the condition of the ewe.' The author of this treatise has uniformly observed, that in every favourable season, when his stock was in high condition, he had a much larger number of female lambs than of males; and in one of the most favourable seasons that has occurred during his own personal experience, the female lambs exceeded the males to the number of ninety, in a flock of 600 ewes. The ewes had no artificial food at any season of the year; they lived entirely on the natural grasses of our mountain pastures. They got bog and lea hay in snow-storms, but nothing else.

GENERAL MANAGEMENT.

The management of sheep must be varied according to the nature and character of the breed, the soil and climate, character of the pastures, natural or artificial, the position of the farm in reference to markets, and whether all the sheep upon the farm can be prepared for the butcher, or must all be sold lean, as is the case with those farmers whose flocks subsist entirely on the natural grasses of our mountain pastures; and whether early lambs would be profitable or otherwise. These and many other circumstances must regulate the proper time for admitting the rams to the ewes; hence the lambing-season, the proper time for washing, shearing, dipping, smearing, &c. Different names are applied to sheep at different periods of their age. A young sheep remains a *lamb* from birth till the first smearing-time. From this till the first clipping it is called a *hog*. From the first to the second clipping it is termed a *gimmer*. It is now called a *young ewe*, till it bears its first lamb. When male sheep are cut, they are denominated *wedders;* and, according to their age, are called wedder-hogs, &c. At three years old, the wedder is in its prime for mutton.

Lambing.

The period at which sheep begin to breed is in the autumn of the second year after birth, when both rams and ewes are at their maturity. In the British Islands, the company of the ram is permitted at the beginning of October. The ewe goes with young about 152 days, or between twenty-one and twenty-two weeks, and consequently the lambing-season is at the beginning of March. It is of high importance that sheep, during gestation, should be managed with peculiar gentleness and care, the rash use of the dog being attended with the most pernicious consequences. The ewes should be well but not overfed, as the ewes being in too high condition greatly increases the risk in lambing. Though parturition, being a natural process, cannot be regarded as a disease, still, in the sheep, as well as in many of our domestic animals, it is attended with some risk; and in certain states of the atmosphere, and ewes in too high condition, the loss is often very considerable from inflammation.

'As the period of parturition approaches,' observes an intelligent writer in the *Penny Cyclopædia*, 'the attention of the shepherd should increase. There should be no *dogging* then, but the ewes should be driven to some sheltered enclosure, and there left as much as possible undisturbed. Should abortion take place with regard to any of them, although it does not spread through the flock as in cattle, yet the ewe should be immediately removed to another enclosure, and small doses of Epsom salts, with gentian and ginger, administered to her, no great quantity of nutritive food being allowed.

'The ewes should now be moved as near home as convenience will permit, in order that they may be under the immediate observation of the lamber. The operation of *clatting*, or the removal of the hair from under the tail and around the udder, should be effected on every long-woolled ewe, otherwise the lamb may be prevented from sucking by means of the dirt which often accumulates there, and the lamber may not be able at all times to ascertain what ewes have actually lambed. The clatting before the approach of winter is a useless, cruel, and dangerous operation.

'The period of lambing having actually commenced, the shepherd must be on the alert, yet not unnecessarily worrying or disturbing the ewes. The process of nature should be permitted quietly to take its course, unless the sufferings of the mother are unusually great, or the progress of the labour has been arrested during several hours, or eighteen or twenty hours or more have passed since the labour commenced. His own experience, or the tuition of his elders, will teach him the course which he must pursue.

'If any of the newly dropped lambs are weak, or scarcely able to stand, he must give them a little of the milk which at these times he should always carry about him, or he must place them in some sheltered warm place; in the course of a little while, the young one will probably be able to join its dam. The lambing-field often presents at this period a strange spectacle. Some of the younger ewes, in the pain and confusion and fright of their first parturition, abandon their lambs. Many of them, when the udder begins to fill, will search out their offspring with unerring precision; others will search in vain for it in every part of the field with incessant and piteous bleating; others, again, will hang over their dead offspring, from which nothing can separate them; while a few, strangely forgetting that they are mothers, will graze unconcernedly with the rest of the flock.

'The shepherd will often have not a little to do in order to reconcile some of the mothers to their twin offspring. The ewe will occasionally refuse to acknowledge one of the lambs. The shepherd will have to reconcile the little one to its unnatural parent, or to find a better mother for it. If the mothers obstinately refuse to do their duty, they must be folded by themselves until they are better disposed; and, on the other hand, if the little one is weak and perverse, it must be repeatedly forced to swallow a portion of her milk, until it acknowledges the food which nature designed for its sustenance.'

Male lambs are cut nine or ten days after birth. Weaning, or removal from the mother, takes place from three to four months after birth, according to circumstances. In weaning, the ewes and lambs must be separated so far that they will not hear the bleatings of each other. The lambs are at first put on the tenderest herbage that can be selected. Some ewes may have so much milk, that the udders will swell when deprived of the lambs, and this requires to be attended to by the shepherd at this trying season of his labours.

Food—Tending—Shelter.

The best kind of food for sheep is nutritious grassy pasture, growing on a dry and firm soil. The sheep is most assiduous in picking up food, and will range over a great space in quest of the herbage which it is fond of. In the Highlands of Scotland, and in Australia, where the herbage is scanty, the sheep-farm requires to be very large: twelve miles in length and breadth is no unusual size of a Highland sheep-farm. In countries liable to be covered with snow in winter, grass, hay, or some other vegetable material must be preserved for the subsistence of the flocks when their ordinary walks are under a snowy mantle. Natural meadow-hay and turnips are used in Scotland for winter keep when ordinary resources fail; and the employment of these, in the case of heavy drifts, sometimes saves large numbers of sheep. If the flock can be conveniently driven to a cleared hay-field, such is done in preference to carrying food to the animals; there should be one field for the rams, and another for the lambs, or for sheep in a weakly condition. A general rule for sheep intended for the butcher is, that they should never be allowed to turn lean, but be kept in a constant state of improvement; and that kind of food should be selected that will bring the animals to the highest profit in the shortest time and at the least expense. In well-managed store-farms, sheep are now allowed many kinds of food little thought of in former times, as sliced turnips, oil-cake, &c.; and are, besides, provided with troughs of pure water, and a trough of salt, that they may lick when their taste leads them to that indulgence. In all artificial feeding, the food should be free of dirt or any insect spawn.

Heedless farmers are sometimes apt to purchase and keep more sheep than they can conveniently feed on their grounds, which causes a serious evil. To overstock a farm, where artificial food cannot be obtained, is one of the most fatal errors a farmer can commit. It does not merely diminish the quantity, but also fouls and deteriorates the quality of the food. A farm may be overstocked for a few years, but death will by and by not only lessen the numbers, but diminish to a great extent the health and productiveness of those that survive. Avarice and ignorance have tempted not a few farmers to carry on this unequal struggle against the laws of nature and humanity for years, but it has always ended, as it ever must, either in the farmer's ruin, or in a reformation of his plan.

The tendency which most sheep have to ramble, renders it necessary for them to be attended by a shepherd and his dog. The duties of a shepherd are very irksome, and require to be performed by a man of firm resolution, good temper, and discretion. To keep the flock within bounds may be troublesome, but much may be done in the way of preventive; and at all events, the sheep must not be harassed and chased as if they were so many wild beasts. Being naturally of a timid and gentle nature, the sheep ought to be treated with a degree of gentleness, and taught rather to look up to their shepherd as a friendly protector than a tyrant. Lazy shepherds, who do not exercise a judicious foresight in keeping the flock to its ground, try to remedy the evil by hounding or driving the dog after the stragglers, besides giving no small toil to their own limbs in running. We are desirous to lay it down as a rule, well known to all good shepherds, that there should be *only a rare and cautious use of the dog*. Much also depends on the dog being of the proper breed, and well trained to his duty. A good dog gives little tongue; he is seldom heard to bark; his great knack consists in getting speedily and quietly round the further extremity of the flock, and then driving them slowly before him in the direction which his master has pointed out. A wave of the hand in a certain direction, and a word, are usually enough as a sign. Under-bred dogs bark at and fly upon the poor animals, chasing them hither and thither without any rational purpose. All such dogs should be destroyed, as unfit for the important duties which they are intended to perform. A first-rate shepherd's dog is invaluable to the store-farmer, and no reasonable price should be grudged to obtain one.

We now proceed to quote a few passages on the 'Winter or Storm Feeding of Sheep,' from an article which appeared in the *North British Agriculturist* in 1853, from the pen of Mr Boyd of Innerleithen, a gentleman who has carefully studied the habits and economy of the sheep. 'That food and shelter form the true basis of all animal existence, cannot be questioned for a moment, and it is therefore altogether astonishing that so little exertion has hitherto been made to procure the food necessary for the winter and spring feeding of the woolly inhabitants of our mountains. Independent of self-interest, the mere considerations of humanity alone ought to be sufficient to awaken in the store-master every energy to adopt such measures as are best calculated to procure food and shelter for his flocks during a storm. We are well aware that the quantity of bog-hay that can now be collected, in consequence of the surface-draining of the mountain pasture, is a mere fractional part of that collected in the days of our forefathers; but we are not less aware, that even in the best cultivated districts of Scotland, there will always be a piece of land which may be advantageously used for the raising of hay, by irrigation or surface-manuring, as an addition to the cultivated farm. In all our mountainous districts, there is an abundance of sloping and low land, barren, or productive of the worst herbage in its natural state, which admits of irrigation, from those innumerable rivers and mountain-streams by which these districts are traversed

. . . . . We have ourselves, on the first of August, seen sheep eat salted ferns with every apparent relish which had been cut while young and succulent, and we may therefore with much propriety conclude that salted well-got natural hay would be eaten with still greater relish, at any season of the year, in particular by the lambing ewes in a cold ungenial spring. We have long been of opinion, that if salted food—and the more miscellaneous the herbage, the better—were given to the flocks more frequently, that it would not only be highly conducive to their general health, but that it would exempt them from many of the diseases which they are heir to, particularly the rot, which not unfrequently makes such fearful havoc amongst the mountain flocks in many districts of country. Few or none will dispute the value of a few turnips for their flocks during a storm. . . . . The practice of sending the young sheep from the mountainous districts to the valley to be fed on turnips for a few months during winter, has been abandoned by many, as they found, to their sad experience, that the teeth of their sheep had been so much injured by eating the frozen turnips, that they were in a great measure rendered unfit for permanent or hill stock. One of the greatest errors that can be committed in the management of stock during a storm, is to be too long in commencing the feeding of the flocks. Once allow them to deteriorate, and it will be found no easy matter to restore them again to their wonted health and condition. We have long advocated the propriety of cultivating the whin and broom for the winter feeding of sheep, which ought to be sown or planted in large semicircles, so that they might serve the threefold purpose of food, shelter, and shade. They fill up the blank in green feeding, between the decay of herbaceous plants in autumn and their renewal in spring, and they afford a nourishment more wholesome and palatable than can be afforded to sheep during that interval, with the additional recommendation of being in general suitable to the soil of our pastoral districts. The *Ulex strictus*, or upright Irish whin, has the greatest number of shoots, and being of a less prickly nature than the French or Scotch varieties, it is on that account more relished by the sheep, but from its tender nature, it is extremely apt to be cut down by frost, when the Scotch and French remain unscathed. It may be necessary to state that the Irish whin is a mere variety of the common plant, and can only be raised by cuttings, and cannot be propagated from seed. The whin ought never to be cut, but portions of it should annually be burned to keep its shoots tender and succulent. "If you want a bush, burn a bush," is one of the truest Scotch proverbs. The natural sap in the stumps of the cut whin keeps oozing out until they become like a piece of seasoned timber, and consequently long before it can be discovered that there is any life in the plant whatever; but very different is that of the burned bush; the stumps, in consequence of the burning, have become in some measure hermetically sealed, and consequently the natural sap is retained, which has the effect of producing numerous and vigorous shoots in an amazingly short period of time. It has long been a well-ascertained fact, that both the whin and the broom possess medicinal properties for the sheep, and in particular act as an antidote for the rot. It may be stated with some truth that whins and broom occupy no space, as it will be found from the shelter they give to the soil, that the quantity of grass is not only much greater, but some weeks earlier than it would have been had there been no whins and broom whatever. The planting of whins and broom may be considered a permanent improvement of no ordinary kind, and therefore, ought to be executed principally, if not wholly, at the expense of the proprietor of the soil. . . . Every shepherd of experience and observation must have noticed how very superior in condition the lambing ewes and sheep were which had been fed on whins and broom during a storm, to those which had been fed on the best natural or artificial hay. The former, from their healthy brown colour, more resemble turnip-fed sheep than mountain stock. They are also all but exempted from diarrhœa, which the hay-fed sheep are apt to be seized with the moment they partake of the moist pasture, and which not unfrequently reduces them to a condition anything but calculated to secure a successful lambing-time. From the difficulty of procuring hay during the winter-storm of 1852, many were induced to thin their plantations, that they might give the fir-tops to their sheep, and not a few of them found to be true what was many years ago pointed out by Mr Little, that the woolly people thrive better upon half hay and half tops than upon whole hay. Salted pea-straw, too, is considered by many superior to either natural or artificial hay, for the storm-feeding of sheep, as they have found from experience that their flocks are less apt to fall off in condition than when fed on the former. It may not be generally known that when pea-straw is given to turnip-feeding sheep, that it has not only the effect of communicating to the flesh of the animal a beautiful tint, but at the same time gives a flavour to the mutton, which is highly relished by every palate. A few bolls of oats ought to be at the command of the shepherd, to assist, if found necessary, in eking out the hay during the protracted winter,

> "When boundless snows the withered heath deform,
> And the dim sun scarce wanders through the storm."

It is then that the whins and broom, and the well-sheltered *stell* and the well-filled rack, reward the diligence of man, and insure the security of his flocks.'

In those districts which are exposed to storms, it is important to afford shelter to the flocks. Where there are jutting or overhanging rocks or bushes, the sheep will crowd under their lee, and so far protect themselves from harm; but where the country is bare, it will be necessary to erect artificial walls or enclosures of turf and stone, to which they can be led in cases of emergency. On the exposed hillsides of Scotland, it is usual to build circular folds, locally termed *stells*, of sufficient size for a *cut*, or parcel of sheep. The stell is a rude enclosure, formed of a stone and turf wall about four feet in height, and is placed on a piece of ground known to be seldom drifted. Besides these, there should be on every sheep-farm ample and conveniently situated folds for the various sortings of sheep, such as for weaning lambs, shearing, and draughting or drawing out any animals required. Such folds are ordinarily constructed of *flakes*, or movable wooden palings, and occasionally of rope-netting.

Washing—Shearing—Wool.

Previous to shearing, all the sheep should be collected, and washed to rid the fleece of impurities. Mr Boyd makes the following observations on washing and shearing:

'We would strongly recommend that the river-washing of sheep should be abandoned, and that for ever; and that pond-washing should invariably be substituted in its place. When a pond is to be constructed for the washing of sheep—which can be executed at no expense whatever by the shepherds—it ought, if possible, to be placed in a situation so as it can be conveniently filled from a river by a conduit; not from a small streamlet supplied by mountain-springs, as the nature and properties of spring-water are anything but calculated to discharge fatty matters from wool. The pond ought rather to be small in size than otherwise, so that the heat of the animal's body would have the effect of raising the temperature of the water, which would aid and assist the washing in no small degree; and so soon as a few scores of sheep have been hand-washed, so as to produce the alkaline solution of sufficient strength, the pond should be fed from the river by the conduit, in a ratio corresponding with the

quantity carried off by the wool of sheep. It has long been a well-ascertained fact, that when wool has been so perfectly washed on the sheep's back, that it can be put to the machinery without being previously *scoured*, it not only requires less oil in the preparation, but is less apt to gilt during the process of manufacture, scours better, and is ultimately an article of greater purity. It is worthy of remark, that a clip of wool which had been *smeared* with butter and rough turpentine, fetched the highest price at one of the Edinburgh wool-sales, solely on account of the admirable result which had been produced in consequence of being *pond-washed*—a result which *river*-washing could not possibly have produced.

'Those who have a knowledge of chemistry, will readily perceive the nature of the changes which are effected in the process of the *pond*-washing of sheep. The *yolk*—which may with some propriety be considered the food and protection of the fleece—being a true soap, mixes with the water, but is decomposed by the earths, in solution in the water, or raised from the bottom of the pond, which combine with the oily portion, and leave the alkaline free, which again combines with the oil remaining in the wool, and also extracts it. On this account, the longer we wash sheep in the same pond, it forms the stronger alkaline solution, and acts more effectually in cleaning the wool, and freeing it from oil. The alkaline solution will also act on the oil or grease in the smearing material in the same manner, converting it into soap soluble in water, and it will consequently be detached from the wool.

'The result of the Edinburgh and Leith wool-sales, by public auction, holds out every inducement to the flock-masters in Scotland, who have not hitherto been very particular in the washing of their sheep, to be more so in future, as the best washed clips at these sales have invariably commanded a higher remuneration to the producer, than those which had been indifferently washed. The practical manufacturer, in estimating the comparative value of a well and ill washed clip of wool, not only takes into account the quality, but the probable reduction which will take place in reducing the ill washed to the same degree of cleanness as the well washed; and from his daily experience in witnessing the various degrees of reduction which take place in the scouring of the fleeces, he is the best qualified to give an opinion on the subject; as also to give an accurate estimate of the expense of the scouring and drying, besides the carriage of so much filth contained in the ill-washed wool, which cannot, at the most moderate calculation, be less than 1s. 6d. a stone.

'It must therefore appear self-evident that the pains-taking farmer pockets 1s. 6d. a stone more than his slovenly neighbour; who, from a self-imposed tax, loses 1s. 6d. a stone upon his clip, which he might easily have saved, and at no cost whatever, as the washing of sheep perfectly and imperfectly is one and the same expense.

'Sheep, after being washed, ought to be driven to a clean pasture-field, and there to remain three or four days before they are clipped, not only that the fleece may be dry, but that the tubes of the staple of the fleece should again be in some measure filled with the yolk or natural secretion which gives the fleece a rich glistening appearance, and in no small measure prevents its gilting during the process of manufacture, and ultimately assists materially in the scouring of the yarn or cloth, and although last, not least, the wool weighs considerably heavier than when clipped the moment the fleece is dry.

'Before commencing the shearing of sheep, they ought to be carefully examined, to ascertain whether or not they are really ready for being shorn. Few greater errors can be committed in the management of stock, than that of too early clipping. The practice is highly injurious both to fat and lean stock, and not only retards their improvement, but not unfrequently originates organic disease, both acute and chronic. . . . Sheep invariably lose weight more rapidly by being exposed to the cold in this manner, than by taking no small portion of their food from them; and it is a well-ascertained fact, that if once you allow animals to deteriorate in condition, it requires no ordinary care and attention to restore them to their wonted health and condition. Experiments have been frequently tried with feeding-sheep, by shearing a portion of them early in the season, and allowing the others to remain unclipped for some time longer; and the results have invariably been in favour of those that were last shorn. It will be readily admitted by those who have a practical knowledge of the management of stock, that if too early clipping of feeding-sheep is injurious, it will be still more so to lean hill-stock, which, owing to their reduced condition, are less able to bear the shock of so sudden a transition. Turnip-fed sheep, and those that have been kept in an improving condition during the winter and spring months, are ready for shearing at any time that may suit the convenience of the store-master, provided the weather is suitable for the operation; but widely different is the case with hill-stock, which, generally speaking, deteriorate in condition during the winter and spring months, and whose wool invariably ceases growing sooner or later, which is in a great measure regulated by the weather or the scarcity of food; and under no consideration whatever ought they to be clipped until the new growth of wool, which appears as the pasture gets more abundant, and which acts as a protection from both heat and cold. It is no matter however favourable the weather may be, and otherwise suitable for the shearing of the flocks, if they are not ready for it. When relieved of their winter covering, while the new growth is so thin and short, they are not unfrequently as much distressed by heat as by cold, and in many situations experience great difficulty in finding a place to shelter them from the burning rays of the sun. Nor, in all our experience, have we ever found that the early shearing of hill-stock had the effect of inducing a rapid or an immediate growth of new wool, but rather the reverse. Every shepherd of experience and observation must have noticed that sheep that were not clipped until the middle of July, have a much more abundant and healthier-looking fleece by the latter end of August, than those that had been shorn some weeks before then. The injurious results produced in consequence of early clipping are not confined to the sheep themselves; the lambs, too, are often seriously injured by the falling off of the milk from the ewes, which early clipping never fails to produce.

'In the management of wool, too much care cannot be bestowed to exclude all impurities in rolling it up, which ought to be done in as firm a manner as possible, but without stretching the fleece.'

Mr Walter Buchanan has written directions to the wool-growers of Australia respecting the management of wool, many of which are of general application:

'In order to assimilate the Australian wool as much as possible with the German, in preparing it for market, the fleeces should not be broken, but merely divested of the breech and stained locks, and so assorted or arranged, that each package may contain fleeces of the same character as to colour, length of staple, fineness of hair, and general quality.

'If the washing has been performed at the same time and place, and with an equal degree of care, the colour of the wool is likely to be uniform, and it will then only be necessary to attend to the separation of the fleeces as to length, fineness, and general quality: but if a larger grower has flocks of different breeds, and fed on different soils, care should be taken that the fleeces be separated, first as to colour, and then again as to length of staple, fineness, &c.

'The fleeces being assorted, should be spread one upon another, the neck of the second fleece being laid upon the tail of the first, and so on alternately, to the extent

of eight or ten fleeces, according to their size and weight. When so spread, the two sides should be folded towards the middle, then rolled together, beginning at each end, and meeting in the centre, and the roll or bundle so formed held together by a slight packthread. The bagging should be of a close, firm, and tough nature. The material hitherto most generally used has been sail-canvas, which very ill resists bad weather on a long voyage; and when received here, even in favourable condition, is so dry and crisp, that it will tear like paper: a thicker, twilled, more flexible, and tough material, would be preferable. The size and form of the package may be in length about nine feet, and width four feet, sewed up on the two long sides and at one end, the other end being left open, and the sheet so formed being suspended, with the open end upwards, to receive the bundles, made up as before directed, which are to be put in one at a time, one of the flat sides of the roll or bundle being put downwards, and so on in succession, being well trod down, until sufficiently filled for the mouth to be closed. This is the German mode of packing; but it is doubtful whether smaller packages, of the dimensions that have been hitherto sent from the two colonies, may not be more convenient for so long a voyage. The operation of screwing should be discontinued where it has been practised, as the screw-pressure, and remaining compressed during the voyage, occasion the wool to be caked and matted together in a manner that is highly prejudicial to its appearance on arrival. The practice also of winding up each fleece separately, and twisting a portion into a band, is productive, in a minor degree, of the same prejudicial effect; and it is to avoid this that the making German bundles of eight or ten fleeces is suggested.'

Smearing—Dipping.

Smearing is a process of anointing the skins of sheep with certain ingredients, principally for the purpose of rendering the animal less liable to injury from winter cold—the unguent being a slight counter-irritant—and of destroying the vermin which lodge among the roots of the wool. Smearing with a mixture of tar and butter was general in Scotland in former times. The proportions varied in different districts; but in general six pounds of butter to a gallon of tar were deemed sufficient for twenty sheep. The time for laying on this salve was in the end of October and beginning of November, before the rams are admitted to the ewes, which, in the mountain farms of Scotland, is in general about the 22d of November. The smearing with butter and tar has very much declined of late years, and other salves have been substituted, as well as baths in which the sheep are 'dipped.' A very extensively used bath is Beg's, which is composed of black soap, potash, sulphur, and a small quantity of arsenic. The comparative merits of 'dipping' and 'salving,' is still a question among farmers. In the *Agricultural Journal* for October 1853, Mr Boyd has advocated salving, and we subjoin a condensed view of his argument:

'The salving of sheep is an operation which has been annually performed upon our mountain flocks from time immemorial, and has for its object not only the protection of the animal, but also of the fleece; and that of "dipping" has alone for its object the killing of insects. The operation is generally performed in the beginning of October, while others defer until the month of February or March, in the hope, from the more recent dipping, that their lambing ewes, as well as their lambs, will be less annoyed with kaids and other insects during the spring months.

'The salve we would with most confidence recommend is the "Artificial Yolk Salve;" and when we consider the chemical nature of the composition, it is the most appropriate name which can be given to it as a new salve; for it is of a similar nature, and possesses the same properties, as the natural yolk existing in the wool. . . . It is composed as follows: 30 pounds butter; 8 pounds black soap; 2 pounds soda ash; 5 bottles refined spirit of tar. To this 21 Scotch pints of stale urine is added, to saponify the butter, as also to assist in the equal spreading of the mixture. When stale urine cannot be had, water may be used, when ammonia will of course require to be added sufficient to saponify the fatty matter contained in the composition. The above is found sufficient to salve 100 sheep; and when salving butter can be purchased at 5d. or 6d.—the price generally paid for it—the whole composition will cost at the rate of 2½d. a head. The mixture requires to be constantly stirred during the time it is administered to the fleece, and at a temperature a little above blood-heat.

'This composition has already been used to a considerable extent in the Border counties, and has been found admirably adapted for repelling external moisture, preventing cutaneous diseases, and killing instantly all insects with which sheep are infested. It is now a well-ascertained fact, that all fatty matters, whether animal or vegetable, when used in the salving of sheep, ought to be saponified, which has the effect of very materially lessening the conducting power of heat, in consequence of the porous nature of the composition, and thereby adding greatly to the comfort of our mountain flocks during a storm or a protracted winter. From the nature and properties of the composition, it has not only the effect of preventing the "gilting" or discoloration of the fleece, but improves its felting properties in a very eminent degree, at the same time communicating to the wool an indescribable kindliness to the touch, which the "dipped" fleece, or that produced in the absence of an oily or saponaceous substance, cannot possibly possess. As the cause may not be generally known which produces the gilting or discoloration of the fleece, it may not be considered out of place to mention the fact, that oily and fatty matters are composed of proximate principles, which, upon being exposed for a certain time, and to a particular temperature, gradually assume a different condition; and instead of being found mild and harmless, they acquire an acid nature from the absorption of oxygen from the air. The names of the proximate principles of such matters are stearine, oleine, and margarine; and by this absorption of oxygen from the air, corresponding acids are formed which produce the colour technically called gilting, which is so much dreaded by the manufacturers of white goods. The sole object the manufacturers have in mixing the oil with a slight quantity of tar, previous to its being administered to the wool, is to prevent the decomposition, which is effected by the action of the creosote and other anti-putrefactive substances which it contains.' A chief virtue of the salving process is its protective effect against wet and cold. All oily matter, it is well known, repels moisture; and a salved sheep is known to shew a marked hardiness in facing all sorts of weather, as compared with one that has been dipped. 'The salved flocks, too, are less apt to be injured by their unclean neighbours than those that have been dipped.

'It has long been a well-ascertained fact, that those who labour in woollen factories get their clothes gradually saturated with oil, and their bodies in consequence are regularly anointed with the same substance, which has the effect of exempting them from many diseases to which their neighbours, who follow other professions, are liable. These results have recently had the concurring testimony of the highest scientific authorities of our country; and we are decidedly of opinion that those of our woolly people which crop the lofty summits of our mountains, which have been judiciously salved with an oily and saponaceous substance, will be less apt to be visited with those diseases to which sheep are heir to, than those that were *dipped*, which are liable to be drenched with every shower that falls, and chilled by every wind that blows.'

Along with the improved condition of the animal, the clip of wool is both greater and of superior quality. 'It is the opinion of some who have written extensively on the nature and properties of wool, that the felting properties depend entirely on the construction. From repeated experiments, we have found that, however perfect the construction of wool may be, if produced in the absence of an oily or saponaceous substance, it cannot possess in an eminent degree the felting or milling properties of a clothing material; and we may here repeat the expressive language of the clothier, "that cloth is either made or marred at the mill."

'Although it is not customary to salve sheep which are to be fed off on turnips, we are, nevertheless, of opinion that they would be much benefited in consequence. It must be consistent with the knowledge of every shepherd of experience and observation, that notwithstanding that the sheep, during the feeding-season, are not only amply supplied with turnips, but with other food of a miscellaneous and nutritious nature, still, if they have not been salved, but merely dipped, a gradual diminution invariably takes place of the yolk during the winter and cold months of spring; so that about the beginning of March the fleece has become dry and sapless, and less sound in staple than the fleece of the salved sheep, and consequently much deteriorated, not only in weight, but in many of its most valuable properties.'

DISEASES OF SHEEP.

The sheep, in a state of domestication, is subject to a great variety of diseases; but the most formidable, and by far the most destructive, is

The Rot.

It is unfortunate that in the early stages of rot the disease gives no external intimation of having commenced its destined fatal career; for it is generally at the beginning of diseases that human skill is most efficacious in arresting their progress. Sheep in the early stages of the rot, however, instead of shewing symptoms of disease and decay, acquire a great tendency to fatten, which has been turned to advantage by Mr Bakewell and others. But after the disease has undermined the general health, the animal becomes listless, and unwilling to move, leaves its companions, and sinks rapidly in flesh; its eye becomes sunk, dull, and glassy; the wool comes easily from the skin; the breath becomes fetid; the bowels variable, at one time loose, with a black purging, and at another costive; the skin becomes yellow, and sometimes spotted with black; emaciation now becomes more rapid; general fever is induced, and death ensues. There are various methods by which practical men endeavour to ascertain the incipient symptoms of the disease, but the two following are the most general:

The first is, by handling the sheep on the small of the back, and if the flesh feel firm and solid, the animal is judged sound; but if the flesh feel flabby and soft, and give a crackling sound when rubbed against the ribs, the animal is unsound. The other method is by examining the small veins at the corners of the eyes, and if filled with yellow serum instead of blood, the animal is pronounced unsound; but the greatest practical tact and talent will not always insure success in discovering the early stages of this insidious disease.

Appearances on Dissection.—The whole cellular tissue is filled with a yellow serous fluid; the muscles are pale, and appear as having been macerated, being soft and flabby; the kidneys are infiltrated, pale, and flaccid; the mesenteric glands distended with a yellow serous fluid; the lungs filled with tubercles; the heart enlarged and softened; the peritoneum thickened; the bowels are often distended with water, and sometimes grown together. But the liver is the primary seat of the disease; its whole structure is in different states of disease; one part is scirrhous and indurated, and another soft and ulcerated; and the biliary ducts are filled with flukes. This appears to be the origin of the disease which has involved so many organs, and effected such a vast derangement of the whole animal frame.

Causes.—In endeavouring to ascertain the cause of this disease, it seems natural to begin by inquiring whether those parasites which are found in such numbers in the biliary ducts of the liver are the cause or effect of the disease. The parasites named the liver-fluke—the *fasciola* of Linnæus, the *Distoma hepaticum* of Radolphi, the *planaria* of Goese—are not peculiar to the sheep, but have been found in the biliary ducts of the goat, deer, ox, horse, ass, hog, dog, rabbit, guinea-pig, and various other animals, and even in the human being. The parasite is of a brownish-yellow colour, and resembles a small sole divested of its fins; in size it may be seen from that of a pin-head to an inch and a quarter in length, and half an inch in breadth. It is supposed to be a hermaphrodite, as no distinction of sex has yet been made out: in scientific language, it increases, like many of the lowly organised animalcules, by self-division and gemmation. The spawn or eggs of this parasite are found in great numbers in the biliary ducts of the liver; these eggs are also found in every part of the intestinal canal, and very often seen in the dung of a sound sheep, though always numerous in that of a diseased one. This animalcule, and many other of the *entozoa*, have never been found out of the intestines; but this is not positive proof that they cannot or do not exist out of the body. Mr Blacklock, in his very valuable treatise on sheep, after laying flat all his opponents, comes to the following conclusion: 'From all this data, the conclusion must at once be drawn, that as living flukes cannot reach the liver from without, they must of necessity be produced only in particular states of the animal they inhabit: how they originate, we cannot of course determine, and this is not the place to hazard a physiological conjecture; but it will be found that their appearance in the bile is always preceded by tuberculous deposits on the lungs and liver.'

That Frommon found the fluke-worm in the fœtus of the sheep, is a strong fact, but not decisive; for Mr Blacklock must know that although he is anatomically correct when he states that there is no direct vascular communication between the fœtal and maternal side, yet the indirect communication may be sufficient. And besides this, Mr Blacklock's own views on this point are extremely unphilosophical, as when he says, 'that living flukes cannot reach the liver from without, they (the flukes) must of necessity be produced only in particular states of the animal they (the flukes) inhabit.' This is just saying that the flukes inhabit the animal before its particular states produce them. This must mean that the eggs of the fluke exist in the liver of the sheep, ready to be hatched by the peculiar states of the animal; and as these eggs could not, according to Mr Blacklock, reach the liver from without, the only other alternative is, that the liver lays the eggs when in a healthy state, and hatches them when diseased. This won't do: equivocal generation is absurd. But the limits prescribed forbid the author pursuing this interesting inquiry further: he must simply state his belief that the ova of the fluke are not generated by the liver of the sheep, but find their way to that organ by means not yet ascertained; but these ova are not vivified in the liver except under certain states of that viscus. The ease with which Mr Bakewell could induce rot in his sheep, by putting them on ground which he had previously flooded for that purpose, shews that other circumstances must concur to produce the disease. It is not caused by scanty food, as has often been alleged, for sheep may be starved to death without producing rot; the fact that the sheep has an extraordinary tendency to acquire fat in the early stages of the disease, shews that the causes act as a stimulant at first, and originate a slight degree of inflammation in the liver, as

the first step in the progress of this fatal disease. But the numerous and well-attested facts now obtained from various climes and countries, lead to the conclusion that the nature of the soil and pastures, and the character of the seasons, are the chief agents in causing rot. This view is confirmed by the fact, that rot is most prevalent in wet seasons, and is nearly confined to lands subject to be occasionally flooded with water at certain seasons of the year, and to soils naturally moist and marshy. Moist and level lands of retentive soil, from which water is slowly evaporated by the sun, and a temperature favourable to the decomposition of vegetable matter—on such lands, when not thoroughly drained, rot may be said to be indigenous; while on lands that are dry and hanging, the disease is unknown. The nature of the plants which the soil produces is not so important as the plants being kept in a morbid state by that degree of moisture and heat favourable to their decomposition. These views will be amply verified by any one who will take an accurate survey of the midland, eastern, and southern counties of England, in which the disease is most destructive. Besides supporting the views here advocated, the following passage from the pen of M. Hammond, the founder of the veterinary school in Egypt, is highly interesting to every sheep-farmer: 'It appears every year in Egypt after the falling of the Nile, and it follows and keeps pace with the subsidence of the waters; desolation and death accompany it wherever it passes, and it annually destroys at least 160,000 sheep. As soon as the waters of the Nile subside, the pastures which were submerged are speedily covered by a tender rushy grass; the sheep are exceedingly fond of it, and they are permitted to feed on it all day long. In the course of a very little time, they begin to get fat, when, if possible, they are sold; their flesh is then exceedingly delicate, but soon after this the disease begins to appear, and the mortality commences. The disease is more frequent and fatal when the sheep are first turned on the newly recovered pasture, than when the ground becomes dried, and the rushy grass harder. But if the sheep pasture in the midst of mud, or on the borders of the marshes and canals, rot attends every step; the rot does not occur in elevated countries, where the sheep feed on dry aromatic herbage. The Bedouin Arabs sell all the sheep which they can before they quit the Nile, for then they are in high and prime condition, after which they lose not a moment in reassembling their flocks and driving them back to the desert.'

Prevention and Treatment.—If the true causes of rot have been accurately given, every farmer has in his own hands the most efficient means for its prevention; on all lands that can be defended from being flooded with water, and on all lands whose levels admit of thorough drainage, the manner and amount of drainage must be determined by the position of the land, whether level or hanging, and by the character of the soil, and the quantity of the moisture to be removed; and on all these points each farmer must decide for himself, or be guided by the advice of a competent judge. The only indispensable rule is, that the drainage must be thorough, in order to be effectual; and if the drainage is carried to this point, and the sheep be provided with food and shelter during snow-storms, the farmer will have the pleasure to see the rot, that dreadful scourge of his flock, disappear. This important point is established by practical men whose testimony cannot be impeached, that there would be no rotten sheep found, even upon the most spongy lands in the country. The treatment of rot is confined to narrow limits, from the curious fact that sheep, in the early stages of rot, acquire fat with singular rapidity; and the best thing the farmer can do, as soon as he finds his flock tainted, is to sell them to the butcher for what they will bring in the market. From the condition of the sheep, this forced sale may be attended with considerable loss; but it will be a loss inferior to that sustained in the fruitless attempt to effect a general cure.

Tainted flocks have recovered, it has been alleged, by being sent to pasture on salt-marshes; but though the efficiency of such pasture were admitted, it is a remedy which only a few farmers could obtain. To change the flock to a more dry and elevated part of the farm, when this is practicable, has been attended with favourable results. The free use of salt is universally admitted to be the best medicine within the reach of the farmer for checking the progress of this deadly disease. That many cures have been effected by the proper use of salt, is attested by persons of the highest character and intelligence. Sir John Sinclair states that at Mr Mosselman's farm at Chenoi, beyond the Wavre, he found that salt was used for sheep, and that by allowing them to lick it, the rot was completely cured. And as the only explanation of sheep taking on fat rapidly, in the early stage of the disease, is, that the digestive organs are stimulated for a time by inflammation of the liver, perhaps the disease might be checked *in limine* by copious bleeding; but the disease can scarcely ever be detected at that period in which bleeding would be proper, and bleeding late in this, as in almost all diseases, is fatal. But in this disease the sheep-farmer must direct his energies and care to the prevention rather than the cure, though some of the remedies just mentioned may be of service at the beginning: yet, from the insidious nature of the disease, it can undermine the constitution, before it is perceived, to an extent that no known remedies can restore; so that every sheep-farmer must rest his hopes of safety not in curatives, but in the vigorous use of the means of prevention.

Braxy.

Braxy, or sickness, is an inflammatory disease, whose ravages are chiefly confined to hogs, and those in the highest condition are most liable to be attacked. This disease is not nearly so destructive as it was formerly, when hogs were hirsled. This has been accounted for by alleging the inexperience of hogs in selecting their food, and their tendency to feed too much on the succulent parts of their pasture. Braxy, being entirely an inflammatory affection, may be excited by a variety of causes, such as drinking cold water in a heated state; any great or sudden change of temperature; by hail, snow, or rain; feeding on soft rank grasses, which are apt to excite fermentation, and by extrication of gas, distend the stomach, thus originating inflammation, and sometimes producing sudden death by pressure on the diaphragm. One very frequent cause of braxy is that kind of frosty mornings which load the pastures with hoarfrost. The hogs, from feeding chiefly on dry and binding pastures at that season of the year (from November till March), eat the succulent spots of grass laden with hoarfrost very greedily; and thus the temperature of the stomach is so suddenly lowered to icy coldness, that violent inflammation is immediately produced, and death often ensues in a few hours. In the list of the causes of braxy, the improper use of the dog must not be omitted. It is clear that nothing is more calculated to produce inflammation than violent heating a sheep by incessant use of the dog at seasons of the year so liable to sudden and great falls of temperature.

Symptoms.—The animal appears uneasy, often lying down and rising up, standing with its head down and back raised, taking no food, but often drinking water; fever then ensues, when the pulse becomes strong and quick, respiration laborious and rapid, the skin hot, and the fleece clapped; the eyes are languid, watery, and half-closed; by and by it ceases to follow the flock, and soon dies.

Appearances on Dissection.—On opening the body, the appearances vary, according to the parts affected. Sometimes only the reed is affected, and all the rest of

the viscera appear perfectly healthy, and the flesh not at all affected. In other cases, the effects of violent inflammation are visible through the whole of the viscera, and the entire flesh of the animal is in a state of rapid putrefaction.

Treatment.—From the nature of the disease, it is obvious that the first and most effective remedy is prompt and copious bleeding from the jugular veins; this being effected, the constipation of the bowels must be removed. The best purgative for this purpose is Epsom salts, two ounces for a dose, dissolved in warm water, and followed by thin warm gruels: these remedies would generally prove effectual if applied at an early stage of the disease; but in a large flock of mountain-sheep the disease is frequently not observed by the shepherd till too late for any remedy. Removal to young grass or turnips has been attended with beneficial results. The best preventive of the disease in mountain-sheep is skilful and attentive herding, by preventing the young sheep from fastening too much on marshy succulent spots, and by seeing they graze regularly over every part of the pasture, and be allowed perfect repose for rumination, undisturbed by the dog.

Sturdy.

The proximate cause of this formidable disease is hydatids (see ZOOLOGY, p. 131) formed in the brain, or an accumulation of water or serum in the ventricles of the same organ. Many ingenious writers, both in France and in our own country, have favoured the public with a few facts and much speculation to account for the manner in which hydatids reach the brain, and the causes of the accumulation of water in the ventricles; but none of these speculations are in the least degree satisfactory, and many of them can be shewn to be absurd, from the known anatomy and physiology of the brain of the sheep. Many plans have been adopted to extract the hydatids from the brain. Hogg, the Ettrick Shepherd, was successful by the use of the wire. He says: 'When I was a youth, I was engaged for many years in herding a large parcel of lambs, whose bleating brought all the sturdies in the neighbourhood to them, and with whom I was exceedingly plagued; but as I was frequently knitting stockings, I fell upon the following plan: I caught every sturdied sheep that I could lay my hands upon, and probed them up the nostrils to the very brain with one of my wires, and I beheld with no small degree of pleasure, that by this simple operation I cured many sheep to different owners; but I kept all my projects to myself, for I had no authority to try my skill on any of them;' and he adds, 'that several years passed before I failed in this operation in any one instance.' Nothing approaching this success, however, has ever attended the operation in the hands of any of Mr Hogg's disciples; though, when the hydatid is situated in the ventricles, or in the upper portion of the brain, some farmers and shepherds have acquired such tact in the use of the wire as to cure considerable numbers.

The use of the trephine is attended with some difficulty and danger. It lays open at once an immense space in the brain to the action of the atmosphere, and its consequent irritation, and hence the risk of inflammation. When the situation of the hydatid can be ascertained by the softening of a portion of the skull, to destroy the vitality of the hydatid by perforating it with the trocar or other sharp instruments, is perhaps the method attended with the least danger of exciting inflammation, and hence the most likely to succeed. But the extent to which the disease must have injured the brain, before the softening of the bone could reveal the position of the hydatid, is an insuperable evil, diminishing the chances of success in any mode of conducting the operation that can be devised. There is no medicine that can justly be regarded as of any avail. But carefully observed and accurately recorded facts may yet throw some light on the remote causes of this formidable disease, under that higher anatomical and physiological knowledge which has within these few years been brought to bear on the diseases of our domestic animals.

Pining.

This disease, it is said, was unknown in this country before the sheep-walks were thoroughly drained and the moles exterminated. If this statement is correct, the cause of the malady must obviously be too dry and binding pasture; and in accordance with this view, constipation of the bowels is always present in this disease. To open the bowels freely, and change to young grass, are the obvious remedies; and when both can be readily applied, they seldom fail of complete success.

Dysentery.

This disease begins with violent discharges from the bowels of a green slimy mixture, which in progress of time becomes mixed with blood. It has often been confounded with diarrhœa, from which it differs in many particulars. Diarrhœa attacks young sheep, particularly hogs, occasioned by a sudden rush of grass in the spring, or from too sudden a change from a scanty to an over-rich pasture; when such are the causes of diarrhœa, the mere change to a drier pasture will effect a cure. But dysentery attacks old sheep, and generally does not commence till June or July. Many writers allege that this disease is highly contagious, but the best established facts do not sustain the allegation. The disease prevails in fouled pastures, and in seasons characterised by a peculiar state of the atmosphere with regard to heat and moisture, a certain combination of which renders the malady so fatal to our army, especially in tropical climates. In the treatment of this disease, bleeding is a proper remedy in an early stage; but if late, gentle purgatives alone must be used: Epsom salts or castor-oil, with twenty-five to thirty drops of laudanum, are the best purgatives. Mr Stevenson also used an infusion of logwood, and doses of ipecacuanha, in numerous cases with great effect.

Trembling.

Trembling, or Louping Ill, in mountain flocks, is a disease caused by cold east winds, which are prevalent in April and May, and at which season this disease, after a bad winter, is often very destructive. The animal sometimes leaps from the ground and falls down dead; but more generally it is seized with trembling, loses the power of its legs, and lies on its side, grinding its teeth, and moving its limbs with great violence. The appearances on dissection are very uniform: great congestion of blood in the liver and lungs, and particularly the heart, which is invariably gorged with dark blood; and the brain is also sometimes congested; the whole flesh of the body is as white as if the animal had been killed by the usual process of bleeding.

These appearances, and various experiments, led the writer of this paper to view the disease as the effect of a lost balance in the circulation: the cold east wind acting on the surface of the animal when she is just beginning to return from the lowest point by the coming grass, drives the blood from the surface, congests the lungs and liver, and overpowers the action of the heart with a rush of dark venous blood. The numbness of the limbs, caused by the heart being unable to send the circulation to the extremities, has led some writers to regard the disease as a kind of palsy.

Treatment.—Copious bleeding in the first stage of the attack will often restore the balance of the circulation; but if the animal has been affected some time, it is often difficult to obtain a sufficient quantity of blood, which has been thrown from the surface upon the heart and other internal organs. In this state, the animal must be put into a tub of hot water at 98°, which will cause the blood to flow, and thus restore the action of the heart, and tend to restore the balance of the circulation. After a sufficient quantity of blood has been

drawn, doses of Epsom salts, dissolved in warm water, and followed with thin warm gruels, must be given till the bowels are freely opened. The prompt application of these remedies on the first attack of the disease would in general be successful; but, like many other diseases of sheep, it is not observed till the action of the heart has become too feeble for any remedies to restore the lost balance of the circulation. A sudden surprise has been found to produce trembling, so that the shepherds cannot be too cautious while turning sheep. The same views of the nature, causes, and treatment of this destructive disease are supported by numerous facts and experiments brought forward by Mr Tod, in his prize essay, published in the *Transactions of the Highland Society of Scotland*.

Foot-rot.

This is a disease most prevalent in luxuriant meadows, and in all soft grassy lands saturated with moisture. The opinions entertained regarding its causes are discordant in the extreme. Some writers contend that it is comparatively a modern disease, and was first mentioned by two French physicians, M. Etienne and M. Leibault, who published some cases of the disease in *La Maison Rustique*, in the year 1529. Lulin says that it was brought from Piedmont to Geneva in the year 1786, and that the foot-rot did not exist among Swiss sheep before that period; and in a report of the management of Flemish sheep in 1763, published by authority, foot-rot is not once mentioned. In our own country, it is mentioned by Sir Anthony Fitzerherbert in the year 1523. But whatever may have been its history and progress in other countries, it was very prevalent in Great Britain in 1749. Ellis, who wrote in that year, says 'that it raged particularly in the counties around the metropolis. The ewes were seized with foot-rot, which was communicated to other sound ewes and to the lambs which they suckled; and most of the meadows are so much infected with this sheep malady, that few of the suckling ewes are ever clear of it in a greater or less degree, and the pain and anguish thereof keeps them poor in flesh, and lessens their milk; so that two or three ewes thus affected give no more milk than one full milch-ewe that is in perfect health.'

It will aid the reader to follow with greater clearness the following discussions regarding the nature and causes of foot-rot, to have first a correct view of the healthy anatomical structure of the foot of the sheep, at least in as far as this very formidable disease is concerned. 'There are some points of importance,' says that eminent veterinary surgeon, Mr Dick, 'to be kept in view, in order to understand properly either the functions of the foot of the sheep, or the nature of the diseases to which it is liable. The foot presents a structure and arrangement of parts well adapted to the natural habits of the animal. It is divided into two digits or toes, which are shod with a hoof composed of different parts, similar in many respects to the hoof of the horse. Each hoof is principally composed of the crust or wall, and the sole. The crust, extending along the outside of the foot round the toe, and turning inwards, is continued about half-way back between each toe on the inside. The sole fills the space on the inferior surface of the hoof between these parts of the crust, and being continued backwards, becomes softer as it proceeds, assuming somewhat the structure of the substance of the frog in the foot of a horse, and performing at the same time analogous functions. The whole hoof, too, is secreted from the vascular tissue underneath. There are, besides, two supplementary digits at the fetlock. Now, this diversity of structure is for particular purposes. The crust, like that in the foot of the horse, being harder and tougher than the sole, keeps up a sharp edge on the outer margin, and is mainly intended to resist the wear and tear to which the foot of the animal is exposed.'

This structure of the foot of the sheep is extremely well adapted to Alpine ranges, which are the native abodes of the sheep in their natural state. 'Dwelling by preference,' in the language of Mr Wilson, 'among the steepest and most inaccessible summits of lofty mountains, among its native fastnesses, it is seen to bound from rock to rock with inconceivable swiftness and agility.'

From these facts, it is easy to perceive how our domestic sheep are subject to foot-rot, when confined to a limited range on soft and rich pastures, and in wet and grassy lands. In these situations, the growth of the crust of the hoof exceeds the wear and tear, and soon overlaps the sole, and in this situation is either rent or broken off, when sand or dirt reaches the vascular parts of the foot, and hence inflammation is produced. The animal then becomes lame, suppuration takes place, and ulcers discharge fetid matter; and if these ulcers go on unchecked, they throw out fungous granulations; and if these be allowed to go on, the hoof falls off. When the disease reaches to this extent, the constitutional disturbance is very great from high inflammatory fever, and the animal rapidly loses flesh, and, if unrelieved, dies of fever and starvation.

Such being the nature and causes of the disease, the author of this paper thinks the views of Mr Dick rest upon a more secure and philosophical foundation than any other writer that has come under his observation; and if these views are admitted, the treatment and means of prevention are very obvious. To pare away all the detached hoof, and dress the diseased part with some caustic, perhaps the muriate of antimony, has the greatest weight of authority. But as prevention is in all cases to be preferred to cure, the shepherd should keep a vigilant eye upon the flock, and pare regularly on lands that require it. By the simple means here recommended, the writer has prevented the disease from injuring his flock of sheep for more than twelve years, though the lands were subject to the disease. But if foot-rot be as virulently infectious as it is affirmed to be by a whole host of writers, many of whom are men of high character and attainments, very different means both of prevention and treatment must be adopted. As the decision of the question, whether foot-rot be infectious or non-infectious, is of great practical importance to every sheep-farmer, the evidence on both sides of the question would require to be stated with perfect candour, in order to arrive at the truth. In so far as evidence has been produced, the argument inclines to the side of those who contend for the non-contagiousness of the disease. Mr Dick very reasonably asks: 'Has any one ever attempted to produce the disease by inoculation? If it is highly infectious, surely it will at once be produced by inoculation. But this is not such an easy matter as one would expect, from a disease which is supposed to infect a whole field, and that, too, even if it be of five hundred acres in extent. Gohier, a French veterinarian, first applied a piece of horn from a diseased foot, covered with the matter, to the sole of a sound foot, without effect; secondly, he rubbed a diseased foot against a sound one, without effect; thirdly, he pared the sound foot, and having applied a piece of diseased hoof, the disease afterwards appeared; but in this case the foot afterwards got well of itself, and there seems to have been a doubt in the mind of Gohier as to whether it was truly foot-rot or not. Other French veterinarians have tried similar experiments, and particularly Vielhan of Tulle, and Favre of Geneva; and although I have not seen an account of their experiments, it is said they succeeded in producing the disease by inoculation. Now, it will be asked, Is not this a sufficient proof of its infectious nature? I answer that it is not. It appears to me that this is a strong proof against it. If it is produced with so much difficulty by the direct application of matter, is it not absurd to suppose that a few sheep with diseased feet should infect a whole field? I have not seen an account of the manner in which

the experiments of the French veterinarians have been performed; I know not what quantity of matter was employed, neither have we any account of counter-experiments, nor whether any were tried to prove if a similar effect would not have been produced by the application of any other morbid matter; for example, whether the matter of grease from the heels of horses, or from thrushes, would not have produced similar effects. I have little doubt of such being the case; that suppuration might be produced by inoculating with that or almost any other matter, if, in the operation, the wound was made sufficiently deep; nor would I doubt that disease would be produced if matter was spread over the foot in sufficient quantity, and applied for a sufficient time.'

In support of these views, Mr Black, farm-overseer to his Grace the Duke of Buccleuch, states that he had thirteen score of black-faced sheep, the greater part of which were affected with foot-rot, and many of them crawling about upon their knees. He turned them into a drier pasture, on which were seven score of Leicester and Cheviot sheep. All of the diseased sheep except four speedily recovered, and not one of the Leicesters or Cheviots was infected. This is a very strong fact, from the pressure of which the contagionists cannot easily escape.

The Scab.

This frequent and very mischievous disease has annoyed the cultivators of sheep in different parts of the world from time immemorial. It is mentioned by Ovid, Livy, and in the *Georgics* it is very graphically described by Virgil. In our own country, it is mentioned by our earliest writers; and in Italy, France, and Germany there is scarcely a writer on sheep who does not describe this prevalent and ruinous disease.

Symptoms.—The sheep becomes restless, scratching itself, tearing off the wool with its teeth, and rubbing violently against any post, stone, or gate. When the skin is carefully examined, there are seen numerous pustules, which, having broken and run together, form large patches of scab. The back and shoulders are generally first affected. The general health of the animal sinks in proportion to the extent of the eruption and the virulence of the disease, and if allowed to proceed unchecked, it brings on general inflammation, and the animal dies in a most miserable condition.

It is now ascertained that this disease in sheep is caused by minute insects of the class *acari*. M. Walz, a German veterinarian, has given a very curious and interesting account of the operations of these acari, which are said to burrow in the skin of the sheep, and reappear again about the sixteenth day with a numerous brood. These young insects commence operations at once, and propagate in the same manner, till the poor sheep sinks under myriads of his destroyers. The work of M. Walz contains drawings of these insects, highly magnified. The subject deserves further investigation, being of great importance to the sheep-farmer.

The treatment of scab is thus rendered very simple—the destruction of the insect which caused it. Infusions of tobacco, hellebore, or arsenic, have all been employed with success. In bad cases, the mercurial ointment has been applied with the happiest effect. A very good recipe is a decoction of tobacco and spirit of turpentine, with a little soft soap and sulphur vivum.

The only caution necessary to be given in the use of any of these remedies is, to take care that they be brought thoroughly in contact with every part of the skin of the affected animal, lest any of the burrowed acari escape. And all folds or sheds in which infected sheep have been confined, and all gates, posts, and other rubbing-places, must undergo thorough purification. Besides the acari, sheep are liable to be attacked by various other insects, such as the flesh-fly, and a species of aphis called the sheep-louse. The maggot only prevails in the moist and warm summer months, but increases in numbers with amazing rapidity, and requires great watchfulness on the part of the shepherd, as they soon destroy a large portion of the skin and flesh of the sheep if unchecked. The aphis also creates great irritation; but both species are easily destroyed by any of the preparations already detailed. The tick (*Acarus redurius*) is also a very formidable insect to sheep. It almost buries itself in the skin, and adheres so firmly by six legs, very muscular and powerful, and so armed with serrated claws, that it can scarcely be disengaged from its hold, but will yield, like most of the parasites which infest the sheep, to the application of a mercurial preparation.

Statistics.—The number of sheep in the United Kingdom is estimated at 20,000,000, producing 100,000,000 pounds of wool. The imports of wool amount to about as much more; but some 24,000,000 pounds of the imports are again exported, along with 13,000,000 pounds of home growth. About half the wool imported into Great Britain comes from Australia, and one-third from the Cape of Good Hope. India and China come next in point of quantity, but the heat of the climate renders the wool harsh and hairy. Most of the fine wool for the manufacture of broadcloth was at one time derived from Saxony and other German states, where the merino breed of sheep is cultivated with great success. But this trade has fallen from 30,000 bales in 1830, to 18,000 in 1856, chiefly owing to the increasing supply of fine merino wool from Australia. The total number of sheep in the Australian colonies was stated in 1854 at 17,000,000; and is every year on the increase. The weight of a fleece of wool is from 1½ to 8½ pounds, and the value varies, according to the quality and state of cleanness, from 6d. to 3s.; that of clean Australian wool may be stated at 2s. 6d.

THE GOAT.

Goats form one of the families of the *Ruminant* order of mammalia. The common domesticated goat is usually about the size of the sheep, though less round in form, and is marked by keen eyes, long hair, and generally bent horns. The males, called familiarly in England *billies*, have a long beard; but the females, or *nannies*, are seldom provided with that appendage. Whether in a state of nature or tamed, the goat is remarkably swift and agile, and will browse fearlessly on the most rugged precipices. We find, from ancient writers, that goats have long formed part of the stock of mountain-herdsmen, and were tended with even greater care in former than in present days. In many respects, indeed, the animal is valuable. Its skin is convertible to several useful purposes, and the flesh of the full-grown goat is good, though scarcely equal in quality to that of the sheep. But it is for the milk chiefly that the goat is prized; the qualities of that secretion being not only very nutritious, but even medicinal. Where cottagers have not the means of keeping a cow, a goat will be found a very useful animal, being easily fed, and contented with grasses which are rejected by the cow and the sheep. To those peasants who live in the neighbourhood of mountainous countries, the trouble and expense of keeping a couple of goats will be nothing, as they will find sufficient nourishment in the most heathy, rough, or barren grounds. Heaths, also, which are unfit for any kind of pasture, will afford this animal an ample supply of food; and it requires no care or attention, easily providing for itself proper and sufficient food. In some countries, goats render considerable service to mankind, the flesh of the old ones being salted as winter provision, and the milk is used in many places for the making of cheese. The flesh of the kid is highly palatable, being equal, if not superior in flavour, to the most delicate lamb.

In Britain, the goat produces generally two young

at a time; sometimes three, rarely four. In warmer climates, it is more prolific, and produces four or five at once, though the breed is found to degenerate. The time of gestation is five months. The male is capable of propagating at one year old, and the female at seven months; but the fruits of a generation so premature are generally weak and defective; their best time is at the age of two years, or eighteen months at earliest. A goat is accounted old at six years, although its life sometimes extends to fifteen.

If goats are properly trained, they will return to their owners twice a day to be milked, and prefer sleeping under a roof when accustomed to it. The milk of the goat is sweet, and not so apt to curdle upon the stomach as that of the cow; it is therefore preferable for those whose digestion is but weak. The peculiarity of this animal's food gives the milk a flavour different from that of either the cow or the sheep; for, as it generally feeds upon shrubby pastures and heathy mountains, there is a savoury mildness in the taste, very pleasing to such as are fond of that aliment. The quantity of milk produced daily by a goat is from three half-pints to a quart, which yields rich and excellent cream. If properly attended to, a goat will yield milk for eleven months in the year. In several parts of Switzerland, Wales, and the Highlands of Scotland, the goat is the chief possession of the inhabitants. On those mountains where no other useful animal could find subsistence, the goat contrives to glean sufficient living, and supplies the hardy natives with what they consider a varied luxury. They lie upon beds made of their skins, which are soft, clean, and wholesome; they live upon their milk, with oat-bread; they convert a part of it into butter, and some into cheese; and the flesh furnishes an excellent food, if killed in the proper season, and salted. They are fattened in the same manner as sheep; but taking every precaution, their flesh is never so good or so sweet in our climate as that of mutton. It is otherwise between the tropics. The sheep there becomes flabby and lean, while the flesh of the goat rather seems to improve, and in some places is cultivated in preference to that of the sheep. The cream of goat's milk coagulates as easily as that of cow's, and yields a larger proportion of curd. The cheese is of an excellent quality, and high flavoured; and although to appearance it looks poor, it has a very delicate relish, and strongly resembles Parmesan cheese. Some farmers have been in the practice of adding a little goat's milk to that of cow's, which materially improves the flavour. In winter, when native food becomes scarce, the goat will feed upon turnip-peelings, potato-peelings, cabbage-leaves, and other refuse of a house. In addition to the other products yielded by the goat, its tallow, we should mention, is also an article of some importance. It is much purer and finer than that of sheep, and brings a high price, being calculated to make candles of a very superior quality.

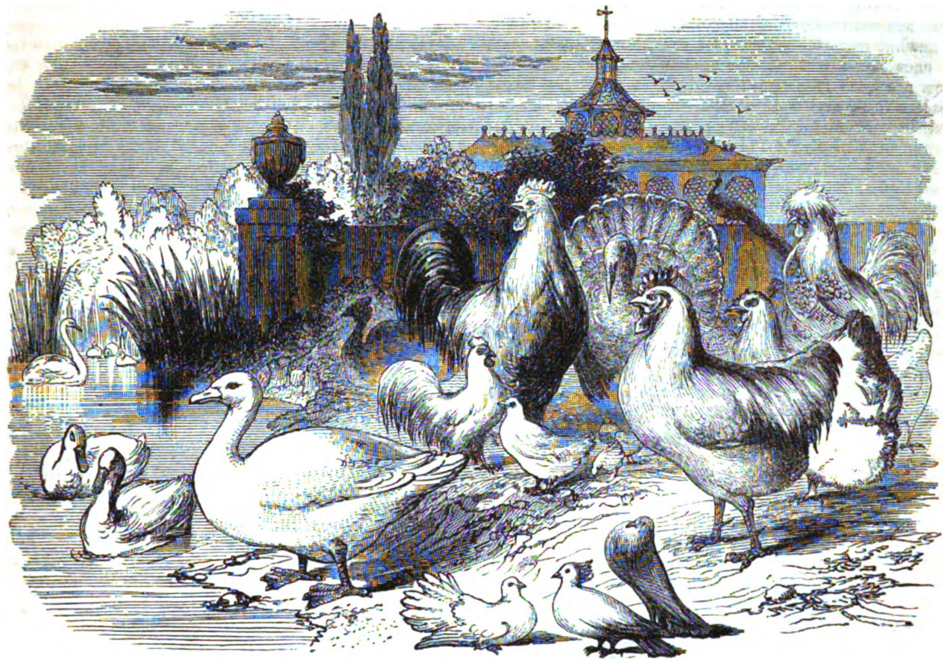
Cobbett advocates the keeping of a goat by cottagers. 'There is one great inconvenience belonging to goats—that is, they bark all young trees that they come near; so that if they get into a garden, they destroy everything. But there are seldom trees on commons except such as are too large to be injured by goats; and I can see no reason against keeping a goat where a cow cannot be kept. Nothing is so hardy; nothing is so little nice as to its food. Goats will pick peelings out of the kennel and eat them. They will eat mouldy bread or biscuit, fusty hay, and almost rotten straw, furze bushes, heath thistles, and indeed what will they not eat, when they will make a hearty meal on *paper*, brown or white, printed on or not printed on, and give milk all the while! They will lie in any dog-hole. They do very well clogged, or stumped out. And then they are very healthy things into the bargain, however closely they may be confined. When sea-voyages are so boisterous as to kill geese, ducks, fowls, and almost pigs, the goats are well and lively; and when no dog of any kind can keep the deck for a minute, a goat will skip about upon it as bold as brass.'

In Britain, no attempts have been made, at least successfully, to introduce foreign breeds of goats, although in France this has been done to a considerable extent. The Cashmere goat, famous for its long silky hair or wool, has been brought to the country mentioned, and there bred with the Tibet goat, a hardier species, but almost equally esteemed for its wool. The manufactures producible from this material, as the Cashmere shawls have long testified, are scarcely to be surpassed for fineness, and yield immense prices. It is probable that, in our warmest districts, a cross of these foreign goats with the common breed might be successfully and advantageously effected.

THE ALPACA.

This animal, an inhabitant of the Andes, below the line of perpetual snow, belongs properly to the family of the *Camelidæ*. Naturalists are not agreed whether it is a distinct species, or merely a variety of the Llama, which was used as a beast of burden by the native Peruvians. The Paco, or Alpaca, has the wool or long hair more developed than the other species or varieties, whichever they may be. The wool is much prized for its silky fineness, length, and lustrous appearance. More than 2,000,000 pounds of Alpaca wool are now annually imported into Britain, where it is used in the manufacture of shawls, coat-linings, cloth for warm climates, umbrellas, &c. Some years ago, attempts were made to naturalise these animals in Britain, but with little success. They are even said to be diminishing in number in their native country, and to threaten, before long, to become extinct.

The Alpaca.



Poultry.

PIGS—RABBITS—POULTRY—CAGE-BIRDS.

PIGS.

TO the humbler classes of society, the pig is only second in importance to the cow. As an object of natural history, it ranks with the *Pachydermata*, or thick-skinned order of the Mammalia—the hog, wild-boar, and probably also the peccary of South America, being varieties of the same family (see ZOOLOGY, p. 183). The most remarkable characteristic of the common pig is its long roundish snout, furnished with a strong cartilage at the extremity, for the purpose of grubbing in the earth for roots and other kinds of food. The feet are cloven, and each possesses four toes, two of which are large, and furnished with stout hoofs, the other two being small, posteriorly situated, and scarcely touching the ground. The body is of a cylindrical form, low set, and thinly covered with bristles, which rise into a strong mane in many of the varieties. The tail is small, short, and in general twisted, and in some varieties is altogether wanting; the ears are either large and pendulous, or short and pointed. The jaws of the pig are powerful; and the teeth with which they are furnished are very formidable, particularly in the wild varieties. Swine do not ruminate (chew the cud); and from this and other peculiarities, they can feed either on vegetable or animal substances—thus forming a kind of link between the herbivorous and carnivorous classes of animals. They are, in fact, omnivorous, and as scarcely any sort of food comes amiss to them, the term 'voracious' is aptly applied to them.

BREEDS—GENERAL MANAGEMENT.

The breeds of pigs most esteemed in Great Britain are the Berkshire, Chinese, and Improved Essex. These are also the breeds best marked by distinctive features; though by crossings, and peculiarities of feeding and position, varieties differing in a slight degree from one another have been raised up in almost every county in England. The Berkshire breed, the parent stock of most of them, is of a reddish-brown tint, with black spots; moderately large ears, inclining forward, but erect; is deep in the body, with short legs and small bone; arrives early at maturity, fattens easily, and with remarkable rapidity. This variety, under good management, grows to an enormous weight. Culley mentions a Berkshire hog, fed by Mr Lawton of Cheshire, which measured, from the point of the snout to the tail, nine feet eight inches; its height at the shoulder was four feet five inches and a half. When living, this huge animal weighed twelve hundredweights two quarters and ten pounds; and when slaughtered, cleaned, and otherwise dressed by the butcher, ten hundredweights three quarters and eleven pounds, or eighty-six stones eleven pounds! The Chinese breed, generally speaking, is of small size. 'The body,' says a good authority, 'is very nearly a perfect cylinder in form; the back slopes from the head, and is hollow; while the belly, on the other hand, is pendulous, and in a fat specimen, almost touches the ground; the ear is small and short, inclines to be semi-erect, and usually lies rather backward; the bone is small, the legs fine and short; the bristles are scarcely deserving of the name, being so soft as rather to resemble hair; the

colour is usually white, sometimes black, and occasionally piebald. The white sort are deemed preferable, from the superior delicacy of their flesh. The face and head are unlike those of any other description of swine, somewhat resembling those of a calf; hence this variety, if once seen, will not be readily forgotten. Chinese hogs are good feeders, arrive early at maturity, fatten on less food, and with similar feeding, become fatter and heavier within a given time than any of our European varieties.' The recently Improved Essex ranks high, for certain purposes, amongst our British breeds of swine. The improvement is said to be due to a cross between the old Essex and the Neapolitan pig; but it is probable also that the Chinese or Berkshire has had something to do in the work of regeneration. The Essex pig is described as up-eared; has a long sharp head; a long and flat carcass, with small bone; colour most frequently black, or black and white; and skin delicate, and almost bare of hair. He is a rapid feeder, but requires a greater proportion of food than the weight he attains to justifies; besides which, he has the character of being restless and discontented. The sows are good breeders, and produce litters of from eight to twelve; but they have the character of being indifferent nurses.

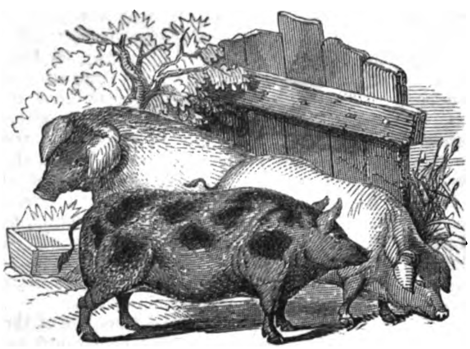


Fig. 1.—Old British—Berkshire—Chinese.

Besides the above varieties—which are at present the favourites at our agricultural exhibitions—the gigantic white and black breed of Cheshire, the white pigs of Suffolk and Hampshire, and the piebald hogs of Sussex and Shropshire, may be mentioned as the best known among the district-breeds of England. They are coarser, generally speaking, than the Berkshire and Chinese. Both of these have been pretty extensively introduced into Scotland, where a less valuable white breed appears to have been earlier located, if not indigenous. There is also a small gray pig, apparently aboriginal, which feeds in herds on the natural pasture on the Highland hills, and furnishes very sweet flesh. By artificial feeding, it can be raised to a considerable bulk. But the breed most commonly esteemed both in England and Scotland is a mixture of the Chinese dark-coloured swine with the Berkshire, or some of the large varieties of British swine. This cross possesses many good qualities, and is peculiarly prolific. Either belonging or allied to the Berkshire variety is the Hampshire *brock*, a small black pig suitable for cottagers, for it is easily fed and fattened, and is therefore highly esteemed. In Ireland, the native pig is described as 'tall, long-legged, bony, heavy-eared, coarse-haired, and by no means possessing half so much the appearance of domestic swine as they do of the wild-boar.' The breed, however, has been greatly improved of late years, and the old unprofitable stock is rapidly disappearing. The improved Irish breeds are now so nearly alike to those of England, that they are not readily distinguishable from each other.

Choice of a Pig.

By whatever name the crop or breed may be called, the following *points* are enumerated by Mr Richardson as those by which the rearer should be guided in his choice of a pig: 'In the first place, sufficient depth of carcass, and such an elongation of body as will insure a sufficient lateral expansion. Let the loin and breast be broad. The breadth of the former denotes good room for the play of the lungs, and a consequent free and healthy circulation, essential to the thriving or fattening of any animal. The bones should be small, and the joints fine. Nothing is more indicative of high breeding than this; and the legs should be no longer than, when fully fat, would just prevent the animal's belly from trailing upon the ground. The leg is the least profitable portion of the hog, and we therefore require no more of it than is absolutely necessary for the support of the rest. See that the feet be firm and sound; that the toes lie well together, and press straightly upon the ground; as also that the claws are even, upright, and healthy. Many say that the form of the head is of little or no consequence, and that a good pig may have an ugly head, it being no affair of anybody but the animal himself which has to carry it; but I regard the head of all animals as one of the very principal points in which pure or impure breeding will be most obviously indicated. A high-bred animal will invariably be found to arrive more speedily at maturity, to take flesh earlier, and with greater facility, and altogether to turn out more profitably than one of questionable or impure stock; and such being the case, I consider that the head of the hog is by no means a point to be overlooked by the intending purchaser. The description of head most likely to promise, or rather to be the concomitant of, high-breeding, is one not carrying heavy bone, not too flat on the forehead, or possessing too elongated a snout—indeed, the snout should, on the other hand, be short, and the forehead rather convex, recurving upwards; the ear, while pendulous, should also be inclining somewhat forward, and at the same time light and thin. Nor would I have the buyer pass over even the *carriage* of a pig. If this be dull, heavy, and dejected, I would be disposed to reject him, on suspicion of ill health, if not of some concealed disorder actually existing, or just about to break forth; and there cannot be a more unfavourable symptom than a hung-down, slouching head, carried as though it were about to be employed as a fifth leg. Of course, if you are purchasing a fat hog for slaughter, or a sow heavy with young, you are scarcely to look for much sprightliness of deportment; but I am alluding more particularly to the purchase of young stores, the more general, because the more profitable, branch of pig management. Nor is colour to be altogether lost sight of. In the case of pigs, I would, as in reference to any other description of live-stock, prefer those colours which are characteristic of our most esteemed breeds. If the hair be scant, I would look for black, as denoting connection with the delicate Neapolitan; but if too bare of hair, I would be disposed to apprehend too intimate alliance with that variety, and a consequent want of hardihood, that, however unimportant, if pork be the object, renders such animals hazardous speculations as stores, from their extreme susceptibility of cold, and consequent liability to disease. If white, and not too *small*, I would like them as exhibiting connection with the Chinese. If light or sandy, or red with black marks, I would recognise our favourite Berkshire; and so on with reference to every possible variety of hue. These observations may appear trivial; but I can assure my readers that they are the most important I have yet made, and that the intending pig buyer will find his account in attending to them.'

Breeding—Littering.

As in the case of other domesticated animals, so with the pig—a perfect, profitable race cannot be maintained without careful and judicious breeding. 'In selecting the parents of your stock,' says the authority above quoted, 'you must diligently bear in mind the precise objects you may have in view—whether the rearing for pork or bacon; and whether you desire to meet the earliest market, and thus realise a certain profit with the least possible outlay of money, or loss of time; or whether you mean to be contented to await a heavier, although somewhat protracted return. If bacon and the late market be your object, you will do well to select the large and heavy varieties, taking care to ascertain that the breed has the character of being at once possessed of those qualities most likely to insure a heavy return—namely, *growth* and *facility* of taking fat. If, on the other hand, your object be to produce pork, you will of course find your account in the smaller varieties; such as arrive with greatest rapidity at maturity, and which are likely to produce the most delicate flesh. In producing *pork*, it is not advisable that it be too fat, without a corresponding proportion of lean; and on this account I would recommend that you rather take a cross-bred sow than a pure Chinese stock, from which the over-fattening results might most naturally be expected.

'In every case, whether your object be pork or bacon, the points to be looked for are—in the Sow, a small, lively head, a broad and deep chest, round ribs, capacious barrel, a haunch falling almost to the hough, deep and broad loin, ample hips, and considerable *length* of body in proportion to its height. One qualification should ever be kept in view, and perhaps should be the first point to which the attention should be directed; namely, the *smallness of bone*. Let the Boar be less in size than the sow, shorter and more compact in form, with a raised and brawny neck, lively eye, small head, firm, hard flesh, and his neck well furnished with bristles; in other respects, look for the same points as I have described in reference to the sow. Breeding within too close degrees of consanguinity, or, as it is technically termed, *breeding in and in*, is calculated to produce degeneracy in size, and also to impair the animal's fertility; it is therefore to be avoided, although some breeders maintain that a first cross does no harm, but, on the contrary, that it produces offspring which are predisposed to arrive earlier at maturity, and take fat with greater facility. This may in some instances be the case: it is so with horned cattle; but as far as swine are concerned, it is not my own experience, and I still adhere to the recommendation I have given. Differences of opinion also exist as to the precise age at which breeding is most advisable. Pigs, if permitted, breed at the early age of six or seven months; but this is a practice not to be recommended. My advice is, to let the female be *at least* one year old, and the male *at least* eighteen months; but if the former have attained her second year, and the latter his third, a vigorous and numerous offspring are more likely to result.'

The sow is very prolific, compared with other large-sized quadrupeds, and for that end is provided with from twelve to sixteen teats. Her period of gestation is sixteen weeks; the number of young varies considerably, being frequently below ten, and occasionally rising to twenty. The young pig is exceedingly delicate; and the brood sow should not be allowed to farrow in winter, but in spring and autumn, when the weather is less severe and food more abundant. Another peril to the litter arises from the semi-carnivorous habits of the mother, which lead her to forget the dues of nature, and devour her own brood. She ought, therefore, to be well watched, and fed abundantly at such periods. The male, for the same reason, must be excluded altogether. Not unfrequently, moreover, the young are crushed to death by the mother, in consequence of their nestling unseen below the straw. To prevent this risk, a small quantity only of straw, dry and short, should be placed below them. The young are weaned when six weeks old; and after weaning, it is essentially necessary to feed them with meal and milk, or meal and water.

Many persons labour under the notion that swine, while breeding, should be kept lean; but nothing can be more erroneous; for, after farrowing, great part of those juices which would be converted into milk, were she in good condition, will naturally go towards nourishing her system. When required for the purpose of fattening, the male young pigs are cut, and the females spayed, which is an analogous process. These operations should always be intrusted to a farrier or other properly qualified person. At weaning-time, it is also customary to 'ring' the young pigs; that is, to insert a ring of iron in the cartilage of the nose, to prevent the animal from grubbing and turning up the floor of the piggery. In pigs intended to be turned to the woods or fields, this process is especially necessary; and where requisite, is preferable to the barbarous and less effectual plan of cutting off the cartilage altogether.

Pig-houses.

The opinion which once almost universally obtained amongst agriculturists and others, that any place was fit enough, and any treatment good enough, for pigs, is fast becoming exploded; contrary to popular belief, pigs are cleanly animals, and if kept in clean sties and supplied with clean litter, will soon shew that they are so. When the food given them, and everything about them, is filthy, it is folly to expect that their habits will be any other than filthy too. Let us, then, beseech all pig-keepers under whose eye this sheet may come, to preserve the sty in the driest and cleanest condition possible, to change the straw frequently, and to curry the skin of the pig at least once a week. By doing so, without a particle of additional food, the animal will thrive and fatten to a very superior degree, while the flesh will be more pure and delicate.

Pigsties, as arranged in a first-class farm, are of three kinds—for breeding, for feeding, and for weaned pigs. For the first, a sty of six square feet will be sufficient, opening into a yard of the same dimensions, in which the feeding-troughs are placed. The feeding pigsty, if four feet square, with a yard of the same dimensions, will accommodate two pigs; the yard and sty for weaned pigs should be some twenty or twenty-five feet square. The yards of all should be in such a position as to have plenty of sun; pigs delight to bask in his beams. As sows are fond of roaming, and easily open doors not well hinged, Mr Stephens recommends grooves to be cut in the front wall of the yard on each side of the doorway, into which a timber-door slides. No sow, however cunning, will be able to force this. The floors of the inner compartments should be well boarded; that of the yard, paved or flagged; the walls should be hollow; and due means should be taken to catch and convey the liquid manure to the tank. An excellent form of feeding-trough is now much used. That part of the trough in the inside of the yard is divided with partitions, reaching some distance into the yard, so that each pig can quietly take his meal without being forced away by a stronger animal, as is often the case in ordinary troughs, where they all feed in common. Another contrivance is also attached, by which the usual inconvenience occasioned to the attendant in filling the ordinary trough, is obviated. Part of the trough being outside the sty, a swing-door or iron plate is suspended on hinges from its upper end; when this is pushed forward towards the yard-side of the trough, and kept in this position by a catch, the pigs cannot obtain entrance; the whole of the trough is therefore exposed to the attendant, so that he can easily place

the food without being annoyed by the pigs. When filled, the swing-door is pulled towards the outside, and there kept by the catch, and the pigs have free access to the trough. The form of feeding-trough on this principle is shewn in the annexed figure. It is built

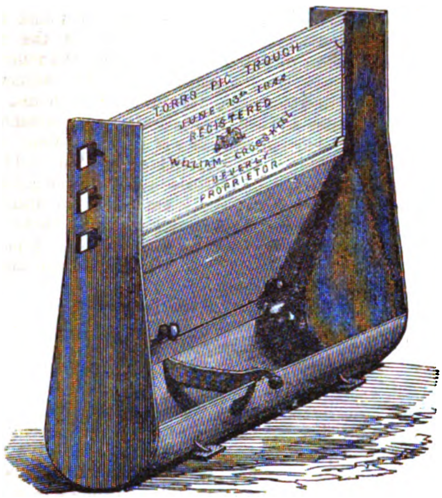

Fig. 2.—Crosskill's Feeding-trough.

in the wall of the sty, and may be used to feed pigs on either side. A good form of feeding-trough for a yard would be a circular one, divided into compartments; these being extended radially for some distance, forming a series of stalls into which one pig only could gain admittance. The cut represents Ransomes

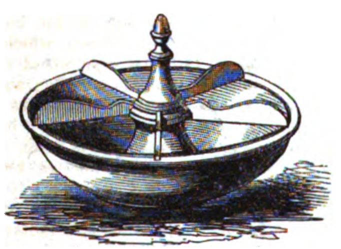

Fig. 3.—Circular Pig-trouga.

and Sims' circular trough for feeding pigs in an open court.

Swine in a domesticated state require to be kept very dry and warm, otherwise they will never thrive. It will be noticed that in cold weather they invariably bury themselves among the straw and litter with which they are supplied as bedding, thus pointing out their natural desire for heat. Keep plenty of straw both in the pig-house and its court, in order to absorb moisture or dung, and let all be raked out regularly and renewed.

Feeding.

In rural situations, where extensive woods exist, and where the grass is otherwise of no value, the feeding and breeding of pigs will be found very profitable to the cottager; for, where they have a wide range, they will require little food save what they find for themselves in grazing under the trees, and in digging for worms and roots of various kinds—for which latter operation their long and strong snouts peculiarly fit them. Artificial feeding is only resorted to in winter, and when the pigs are to be fattened for the market or table. It is more common, however, for the cottager to keep one or two pigs entirely within a sty, to add to the means of subsistence of his own family; and even when kept with this limited view, the pig is a creature of no little consequence. As Cobbett acutely and pithily observes: 'The sight of a flitch or two of bacon on the rack tends more to keep a poor man from poaching and stealing, than whole volumes of penal statutes. They are great softeners of the temper, and promoters of domestic harmony.'

When a young pig is to be purchased for feeding and killing, it is advisable to buy one which will be about sixteen months old at Christmas—that or some time in January being the preferable period of slaughtering the animal. Unless for delicate pork, it should not be killed less than a year old. During the summer, the pig may be fed on any refuse from the kitchen or garden, including turnip and potato parings, table-waste, cabbage-leaves, &c.; but if barley-dust, or grains from a distillery, can be economically procured, either forms a good article of diet. Let it be kept in remembrance that the finer the feeding, the finer will be the pork. The food should, at all events, be of a vegetable kind, or principally so; nothing beyond refuse from the table being advisable in the shape of animal food. Whatever be given, let it be offered in small quantities, and frequently, it being a matter of importance never to allow the pig to become violently hungry. The half-starving system of feeding is poor policy, and is repaid by a lank poor carcass, scarcely worth killing.

Farmers possess great advantages for feeding pigs: the straw-yard of itself affords continual support to them; and many pigs reach the age of one year without having received any food but what they themselves have gathered, yet are in good condition. What with the sweepings of the barn, and the straw, turnips, carrots, and clover, lying about a steading, with the refuse of the kitchen, a farmer, it has been calculated, may sustain swine in the proportion of one to every seven or eight acres of land under crop, without being conscious of the consumption made by them. In few instances are swine reared in such numbers as to have crops specially laid out for them, though some writers assert that they would yield in such a case greater and readier profits than other live-stock habitually reared in the same way. Where rearing on the large scale is attempted, a proper plant of sheds, courts, and feeding-troughs is erected; and besides the miscellaneous refuse of the farm, special crops of coarse potatoes, cabbage, carrots, and Swedish turnips are grown for the piggery.

About the month of September, the process of fattening pigs should commence, whether they be designed for pork or bacon. If for pork, the fattening need not be carried to the same extent. In either case, a nourishing diet must be given, the only precaution being not to commence feeding too rapidly, otherwise surfeit may be produced. The best materials for feeding are barley and peas meal; and if milk, either skimmed or churned, can be given at the same time, it will greatly facilitate the feeding, and improve the quality of the flesh. Many persons feed their pigs on potatoes; but in that case the flesh is not so solid and good, and the fat is somewhat loose and flabby. Soft meat may do very well for pigs when they are growing, but it is not the food which should be given when they are fed for killing. Those who keep pigs for their own use, generally give them a feed or two of corn daily for fourteen days before they are killed, and give them nothing else but churned or skimmed milk to drink; and for a day before killing, the pig should not get any food. Where people's circumstances will not permit any of the modes of feeding for killing which we have above pointed out, boiled potatoes, mixed with a handful or two of oatmeal, may be resorted to as a substitute. It is undeniable, notwithstanding what has been said above, that the Irish

peasantry produce excellent pork by feeding their pigs almost entirely on potatoes. It is not so fat as the pork produced from peas and barley, but it is on that account the better suited to stomachs unaccustomed to very strong food. Swedish turnips, carrots, and broken corn, with a little bean or peas meal, make an excellent fattening dietary, and can be procured at little more than half the expense of the old potato-and-meal system.

In concluding the subject of feeding, we cannot do better than reiterate the following sound injunctions by Mr Richardson: '1. Avoid foul feeding. 2. Do not omit adding salt in moderate quantities to the mess given—you will find your account in attending to this. 3. Feed at regular intervals. 4. Cleanse the troughs previous to feeding. 5. Do not overfeed; give only as much as will be consumed at a meal. 6. Vary your bill of fare. Variety will create, or, at all events, increase appetite, and it is further most conducive to health. Let your variations be guided by the state of the dung-cast: this should be of a medium consistence, and of a grayish-brown colour. If hard, increase the quantity of bran and succulent roots; if too liquid, diminish or dispense with bran, and let the mess be firmer: if you can add a portion of corn, that which is spoiled, and thus rendered unfit for other purposes, will be found to answer perfectly well. 7. Feed your stock separately, in classes, according to their relative conditions: keep sows in young by themselves; and bacon pigs and porkers by themselves. It is not advisable to keep your stores too high in flesh; for high feeding, however strange it may seem, is calculated to retard development of form and bulk. It is better to feed pigs intended to be put up for bacon *loosely*, and not too abundantly, until they have attained their full stature; you can then bring them into the highest possible condition in an inconceivably short space of time. It is by such a system of management as this that the monstrous swine, their weight exceeding frequently 1200 pounds, or, at all events, half a ton, are raised. 8. Do not neglect to keep your swine clean, dry, and warm. These are essentials, and not a whit less imperative than feeding; for an inferior description of food will, by their aid, succeed far better than the highest will without them. And while I speak of cleanliness, suffer me to reiterate the benefit derivable from washing your pigs; this will repay your trouble manifold.' 9. Watch the markets, and sell when you see a reasonable price before you. To these we may add—when the time arrives for slaughtering, let it be done in a humane and neat style by a butcher, so as to avoid all mangling or injury to the flesh.

[The most approved modes of curing and preparing pork, brawn, bacon, and hams, will be detailed in the number on FOOD—BEVERAGES.]

Diseases.

In a state of nature, the pig is a healthy animal, and even when domesticated, is not readily injured, if treated with anything like common humanity. Cribbed and confined, however; compelled to wallow in filth; exposed indiscriminately to all weathers; now surfeited, and now starved; this day receiving stale food, and to-morrow a diet scalding hot—it is not to be wondered at if the animal should be subjected to the attacks of dangerous and often fatal maladies. The principal diseases to which swine, as thus treated, are liable, are—fever, leprosy, tumours, murrain, measles, foul skin, mange, crackings of the skin, staggers, indigestion or surfeit, lethargy, quincy, inflammation of the lungs, catarrh, and diarrhœa. A large proportion of these, it will at once be seen, is the direct result of want of cleanliness and injudicious feeding, and might be wholly prevented by attending to the directions already given. In cases of fever and other sudden ailments, bleeding, purgatives, and a spare diet, are the safest and surest remedies. Bleeding may be performed by opening the vein behind the ear, or by cutting off a portion of the ears and tail. Castor or linseed oil, Epsom-salts, jalap, and flour of sulphur, are simple purgatives, and can be readily administered in a small mess of enticing food; and when given, should always be followed by a spare and liquid diet. For skin diseases, frequent scrubbings with soap and water, and unguents of tar and sulphur, will be found most effectual. In the case of measles—one of the most common diseases to which pigs are liable—the following recipe has been recommended: Suffer the animal to fast, in the first instance, for twenty-four hours, and then administer a warm drink containing a drachm of carbonate of soda, and an ounce of bole armenian; wash the animal, cleanse the sty, and change the bedding; give at every feeding, say thrice a day, thirty grains of flour of sulphur, and ten of nitre. It is to filthiness, combined with a common fault too little thought of—namely, giving the steamed food or wash to the pigs at too high a temperature—that this troublesome malady is generally to be attributed.

RABBITS.

Rabbits belong to the family *Leporidæ*, members of the *Rodentia* or Gnawing Order of animals. Their form and appearance are too well known to require any special description. In a wild state, rabbits live in holes in the earth; and where the proprietor permits of their accumulation for sport or for sale, they collect in great numbers, undermining with their burrows whole plains or tracts of land, and forming what are called *warrens*. Their amazing fecundity renders the keeping of a few of them in a tame state an object of some consequence in cottage economy. The rabbit litters seven times in the year, and generally produces eight young at a time. At the age of five months, the animal begins to breed; and, taking an estimate perfectly within bounds, it is supposed that a pair of wild rabbits, which breed no oftener than seven times in a year, would multiply in the course of four years to the amazing amount of a *million and a quarter*, if the young were preserved. Many of them die, however, being injured by cold and damp, or are devoured by the male or *buck*.

Experienced rabbit-keepers conceive too frequent breeding to be injurious; but even when proper rules are observed in this respect, three domesticated females (*does*) and a buck will give a family a rabbit for dinner at least twice a week. This is a matter of some consequence. By keeping a few of these pretty little creatures, which wild vegetables will almost entirely supply with food, the poor man may derive ten times the benefit to be gained by violating the laws, and poaching on the game-preserves of his rich neighbours. A stock of rabbits is easily set agoing: they may usually be bought under one shilling, and sometimes even at twopence a pair. It is of importance, in making such a purchase, to attend to the varieties which feed kindly and furnish the best flesh.

The short-legged stout rabbits are generally supposed to be the most healthy, and also the best breeders. The large hair-coloured variety is much esteemed by some people; but the white, or white mottled with black or yellow, are more delicate in flesh. The gray, and some of the blacks, approach nearer to the flavour of the wild rabbit than any others. With respect to the colours of these animals, gray is considered the worst of all colours; black is the next in gradation; fawn, and white and gray, hold the third place in estimation; pure white, with red eyes, is by some reckoned equal with, and by others superior to these; tortoise-shell—a rich brown and white, and brown, gray, and white—and black and white rank the highest; a uniform mouse-colour, though

little noticed by fanciers in general, is much admired by a few.

The most important part of the duty of the rabbit-rearer is to erect his rabbit-house or hutch on proper principles. Two objects are particularly necessary to be attended to. The house or rabbitry must be kept always dry and well aired; because the animal, in its natural state, prefers a dry and airy habitation.

We give a sketch illustrative (fig. 4) of the accommodation and arrangements likely to prove efficient aids in rearing rabbits economically and healthily: *aa* is the line of wall of house against which the rabbitry is supposed to be erected, or it may be in an isolated position; *b* is the principal door by which the rabbitry is entered. The hutches are placed as at *f*, *f*, *g*, *g*, with a passage between; the floor of each hutch must be lined with zinc, or made of asphalt or flag, to prevent the animals burrowing. The hutches for the breeding-does, *g*, *g*, *f*, *f*, should be contiguous to those for the young rabbits, *g'*, *f'*; the partitions between them being capable

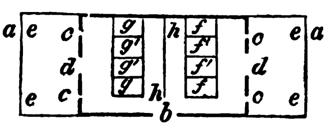

Fig. 4.

of removal; or small doors may be made through which the young rabbits can pass to the breeding-hutches, *g*, *g*, *f*, *f*; or, if necessary, be isolated therefrom. The floors of all the hutches should slope towards the centre of the passage, so as to lead the liquid manure at once to a drain, *h*, *h*, which conveys it away to a small manure-tank. The application of this to the rabbits' recreative-ground, *ee*, *ee*, surrounded by wire-fence, will keep up a fine crop of grass, amongst which they will rejoice. The food is supplied to the hutches through doors opening into the passage. Each hutch should have the front entirely made of wire, to admit plenty of light, which gains admittance through the windows, *c*, *c*; *d*, *d* are the doors through which the rabbits find entrance to the grass-plot, *ee*. Various modifications of this may be made for town-houses, where space is difficult to be had.

On the subject of feeding, the following extract may be offered from the *Boys' Own Book*, a pleasing work addressed to the young: 'If too much food be given at once, the animals will get disgusted with, and refuse it, so that a rabbit may be nearly starved by affording it too great a quantity of food. Most persons feed their rabbits twice, but for our own part we feed ours thrice a day. To a full-grown doe, without a litter, in the morning we give a little hay or dry clover, and a few of such vegetables as are in season; in the afternoon, we put two handfuls of good corn into her trough; and at night, we give her a boiled potato or two, more vegetables, and, if her hutch be clear of what we gave her in the morning, but by no means otherwise, a little more hay or clover. Tea-leaves, in small quantities, well squeezed, may at all times be given, by way of a treat; but it is highly improper to make them a daily substitute for green meat.

'Almost all the vegetables and roots used for the table may be given to rabbits: in preference to all others, we choose celery, parsley, and the roots and tops of carrots; and in this choice the animals themselves heartily agree with us; lettuces, the leaves, and, what are much better, the stumps of cabbages and cauliflowers, they eat with avidity, but these must be given to them with a sparing hand; turnips, parsnips, and even potatoes in a raw state, we occasionally afford our stock, on an emergency, when better roots or good greens are scarce. In the spring-time, no soft meat is better for them than tares, so that they be not wet; in fact, no green meat ought to be given to rabbits when there is much moisture on its surface. We have heard of some country persons feeding their rabbits on marsh-mallows, but we never did so ourselves. Dandelions, milk-thistles, or sow-thistles, we know, by long experience, they take in preference to all other food, except celery, parsley, and carrots; and nothing, as green meat, we are convinced, can be better for them.

'It must be remembered that a doe will eat nearly twice as much when suckling as at other times; and when her litter begin to eat, the allowance of food must be gradually increased.

'If well fed, and kept warm, does will breed all the year; but most fanciers are contented with five litters in one season, and let them rest during the winter. It is a disadvantage, rather than otherwise, to have above six produced in a litter, as the young rabbits, when that is the case, are almost invariably weak and puny; and even if they be reduced to a moderate number, by removing some of them to the care of another doe, or otherwise, they seldom or never become remarkable for their size or beauty.

When rabbits are to be used as food, it is commonly deemed beneficial to feed them for a short time on hay, and afterwards on shellings and oats, when the flesh will grow very delicate in flavour. As an example of the ordinary extent to which rabbits may be made productive, with common care, the case of a labouring man in the country may be mentioned, who, in a small wooden house enclosed by a railing, fed a batch of rabbits, and killed annually about twenty dozen, still maintaining his stock unbroken. What with the skins, flesh, and sales of the young, he turned the animals to good account; yet he scarcely expended a penny upon their food, and even the care of them was spared to him, when he had once fairly put his children in the way of management.

POULTRY.

Poultry (from *poule*, French for hen) is a term applied to different kinds of large birds in a state of domestication; as the chicken or barn-door fowl, turkey, duck, goose, pea-fowl, and guinea-fowl. The most numerous and important in every respect are

Fowls.

The common fowl is classed by naturalists in the tribe of the *Gallinaceæ*, forming part of the order *Rasores* or Scraping-birds (ZOOLOGY). It is needless to describe minutely the appearance of the barn-door fowl. The most prominent characteristics of the cock, or male bird, are a thin indented comb, with wattles on each side under the beak; a tail rising in an arch, and a great variegation of colours. The female, or hen, is smaller as regards body, comb, and wattles, and her tints are less vivid. The domestication of this useful bird seems to have taken place in the earliest times, and Persia is commonly supposed to have been the country of its origin.

Many varieties have been enumerated as existing in Britain; but the differences betwixt these, in the majority of cases, seem to lie as much in colour and size as in any more important features. The best marked varieties are the following: The Dunghill Fowl, Game Fowl, Dorking Fowl, Polish Fowl, Spanish Fowl, Malay Fowl, Hamburg Fowl, Cochin-China Fowl, and Bantam.

The first of these varieties is a mongrel one, arising from crosses with the other breeds. The best fowls of this sort are of middle size and dark colour, and have white, clean legs; the pure white dunghill fowls are held to be the weakest in constitution, and to lay fewest eggs.

It has been usually agreed to call the game fowl the proper English fowl. The body is erect and slender,

and the colours showy, particularly those of the cock. In comparison with other breeds, the Game bird is like the race-horse beside that which draws the cart and plough. The flesh, moreover, is peculiarly white and delicate in flavour, while, though small, the eggs are also of a very superior quality. There is a peculiarity of disposition, however, in this variety of the domestic fowl, which, while for ages the source of a cruel species of sport, has always impaired the real utility of the creature to a very great degree: we allude to the pugnacious spirit which has gained for the fowl its peculiar name. So strongly marked is this propensity, that broods scarcely feathered are found occasionally to have reduced themselves to utter blindness by reciprocal battling. Even when the breed is crossed and recrossed, a tincture of the love of fighting still remains, rendering such admixtures the source of risk and trouble, though in other respects advantageous. Where persons prefer to have a game-cock in their poultry-yard, their choice, according to the best authorities, should be directed to a bird of one or other of the following colours: dark-red, dark black-breasted red, dark-gray, mealy-gray, and reddish-dun.

The Dorking Fowl is named from a town in Surrey, where it has long been bred in great numbers. It is a large bird, well shaped, with a long capacious body, short legs, and five claws upon each foot instead of four. One spur characterises other breeds of the common fowl, but the Dorking fowl has two spurs on each leg. These distinctive marks seem to be of old standing in peculiar breeds, as both Aristotle and Pliny mention five-toed fowls. Though, from repeated crossings, the Dorking fowls are now found of all colours, white or yellowish-white is supposed to have been the primitive and genuine tint. They lay good-sized eggs, and in great plenty. The Cuckoo and Speckled Dorkings are fine birds, and are held in high repute. Within the last few years, there has been a great run upon Cochin-China fowls; but now that this singular taste is abating, Dorkings are every day gaining upon public favour, and are speedily taking up their old position. They are unquestionably the most useful, and perhaps the most remunerative of all the varieties of the domestic fowl. London is supplied with vast quantities of chickens and capons of this breed. The offal is small in comparison to the flesh, which in flavour is justly held as excellent. The shape, size, and beauty of plumage, together with its hatching properties, should recommend the Dorking to the attention of every poultry-keeper. Different kinds should be kept together, as they are found to pine at an early stage when kept unmixed.

The Poland (Polish or Paduan) Fowl is much valued by breeders, but is seldom found perfectly pure in Britain. The species was imported principally from Holland; and when unmixed, was uniformly of a black colour, with a white crest or tuft of feathers instead of a comb, on the heads of both cock and hen. They are now reared in immense numbers in France and Egypt, the eggs being hatched in the latter country artificially. Their form is plump and deep, and the legs of the best sorts not too long. They are called *everlasting* layers, from the number of eggs produced by them, and from their disinclination to sit and hatch, which office is usually done for their eggs by other hens. The three kinds of Polish fowls in greatest repute are the White-crested Black Polish, Silver-spangled, and Gold-spangled.

The Spanish Fowl is of great size, and lays large eggs. It is of the Polish family, and is almost uniformly marked by a black body, dark legs, white cheeks, and large red combs. In London and its vicinity, the breed is now extremely common, being valued for the size of the eggs; but it is supposed to be inferior in some respects to other breeds, though yielding good food.

The Malay Fowl is one of comparatively rare occurrence in poultry-yards, on account of its inutility to the breeder; it is exceedingly pugnacious. They are tall, handsome birds, and certainly make a figure in the poultry-yard; but their flesh does not bear comparison with that of the Dorking fowl.

The Hamburg Fowl is one of the most beautiful of all the Gallinaceous tribe; there are four distinct varieties, as classified at the Birmingham exhibitions—namely, Golden-pencilled, Silver-pencilled, Golden-spangled, and Silver-spangled.

Mr Edward Lowe of Comberford, near Tamworth, whose success in rearing Hamburg fowls gained him the first prize at one of the Birmingham poultry-exhibitions, gives the following results of his experience: 'I find that a hen, now twelve months old, which has laid about five eggs each week since Christmas, weighs exactly three pounds six ounces; and a cock-bird, ten months old, weighs three pounds five ounces. If in good condition, and at full maturity, the cock should weigh at least four pounds, and the hens three and a half pounds each. I have had them at these weights soon after moulting, and before the hens commence laying; but I find them produce such an excessive number of eggs, that they always feel light in hand compared with their apparent bulk, and no amount of food which they are able to take seems sufficient to keep up their flesh. I have never been able to ascertain the *exact* number of eggs that one hen will lay in a year, but I know that some of them have produced more than 200. Under very favourable circumstances, a single hen might produce at least 250; but I should say about 170 would be the average for any given number of fowls. True-bred Hamburgs never shew any inclination to sit; and this, which is considered by many one of their best qualities, might prove a serious difficulty to many poultry-keepers who are not able to keep another sort of hens as incubators. I keep a good many game fowls, and the two sorts work well together, though of course I am obliged to have them on separate walks, as the Hamburgs are very timid, shy fowls, and easily distressed. When the chickens are produced healthy and right, I always find them endure quite as much hardship as any other. For ornamental as well as useful purposes, the Pencilled Hamburg fowls are certainly unrivalled; and I decidedly give the preference to the Golden variety, because they do not shew the dirt in a wet season so much as the Silver. Their plumage is equalled by none, and their symmetry and quality of flesh are only surpassed by the game fowls; and they are the greatest producers of eggs of any breed we have.'

The Hamburg fowl, from its beauty of plumage and tendency to frequent laying, has gradually become a great favourite amongst poultry-fanciers, and is now pretty widely distributed, not only throughout the British Islands, but over the continent of Europe and the United States.

The Cochin-China Fowl, of which so much has been said, and upon which such sums have, within the last few years, been expended, has created a greater sensation amongst all classes of breeders than any other variety of fowl we know of. The great mania was in 1852, when it was not uncommon to hear of £10, £20, or even £50 and upwards being demanded for a good cock and hen; but latterly that extravagant mania has, like many others, in a great measure ceased; and the market-value of the bird is now such as to place it within the range of the humbler classes of poultry-keepers. In the frontispiece of this treatise, we have given sketches of this and a few other of the principal varieties of domestic fowls. The plumage is gay in colour, and soft and yielding to the touch; in size, strength, and weight, it surpasses every other variety; the comb is of moderate size, and notched, and the wattles double; the head is small and narrow, the legs of medium length, and covered with feathers to the toes. It may be said to be all body and no tail or wings, those appendages being almost wanting; hence the

Cochin-China is by no means so graceful an ornament to the poultry-yard as the Hamburg or Dorking varieties.

As a matter of profit, Cochin-Chinas will be found to yield ample returns to the breeder: the hens are excellent sitters, and their fecundity is surprising: they will sometimes lay an egg per diem for several months in succession, and will hatch and carefully rear several broods of chickens annually; the period of sitting and hatching varies between eighteen and twenty-three days.

The Bantam Fowl is well known for its pugnacious habits, its courageous disposition, small size, and feathered grotesque-looking limbs. It was originally a native of India, and the nankeen-coloured and black birds are the most esteemed. The bantam should have a rose-comb, a full tail, and a lively carriage, and should not weigh above one pound. It has been discovered that the characteristic of feathered legs is not an improvement, the birds with clean bright limbs being the best. The flesh and eggs of this diminutive breed are said to be peculiarly delicate and rich.

The chief varieties of the bantam are the Gold and Silver laced, the White, and the Black.

'The black bantam,' says Dickson, 'is a beautiful example of a great soul in a little body. It is the most pugnacious of its whole tribe. It will drive to a respectful distance great dunghill cocks five times its weight. It is more jealous, irascible, and domineering, in proportion to its size, than the thorough-bred game-cock himself. Its combativeness, too, is manifested at a very early period. Other chickens will fight in sport by the time they are half-grown; but these set to work in good earnest. . . . . The black bantam, in his appearance, is a pleasing little fellow. He should have a full rose-comb, clean and sinewy legs, glossy plumage, with almost metallic lustre, of a different tint to the glancing green of the Spanish fowl, arched and flowing tail, waggish impudent eye, self-satisfied air and gait. The hen is of a duller jetty black, is less knowing in her manner, and I think in every way of inferior capacity. These little black hens have great credit for fulfilling their maternal duties well; but I have found them less affectionate and careful than other bantams. They are great stayers at home, prowling very little about, and therefore are desirable in many situations—such as suburban villas that are surrounded by captious neighbours. They will remain contented with the range of a moderate stable-yard, and the least bit of shrubbery; and will do much good by the consumption of numerous insects. They are reputed good layers during winter; but that will depend on the liberality with which they are fed. Cooks say that their eggs, though small, are "very rich," which means, perhaps, that they contain a greater proportion of yolk than those of larger fowls.'

In concluding this condensed description of the various species of domestic poultry, we would only add that they are now considered most profitable stock; where kept in numbers, and carefully attended to, they soon form a considerable addition to the profits of the dairy-farm; and any of the breeds are valuable to the cottager, even one good laying-hen being a treasure to a humble family.

Hen-house.—The artificial assistance given by the cottager in housing the birds is usually of the scantiest order. The upper part of the space at the door of the cottage, or the *baulks* (loft), is often the nightly roost of two or three hens, and the roadside is their daily walk. Yet, with the petty scraps of food furnished in addition to their own pickings there, these hens will lay good eggs, and produce fine birds. At farm-steadings, it is common for the hens to roost among the beams of the stables or cattle-sheds, and to lay in holes formed by scraping away a portion of lime on the top of the side-walls. Very little pains might give to the humblest families much better and ampler accommodation for poultry. We quote on this subject the directions given in a little work by Mr Peter Boswell of Greenlaw: 'To this purpose a part of the space next the roof, so often unoccupied and useless, might easily be devoted. To accomplish the object, a part of it next the kitchen-fire gable-end should be partitioned off, floored, and fitted up with baulks and laying-places. . . . . An opening of sufficient width should be made in the wall, at the height of the lower ceiling, through which the fowls could be conducted by means of a *hen-ladder*, to the enclosure prepared for them below. There must be a hatchway somewhere, to afford access for the purpose of inspection and cleaning. . . . . This is a location for poultry possessing many advantages. Having their berth immediately above the cottage kitchen, they are secured in a proper degree of dryness and warmth, which in winter, especially with the spring-hatched pullets, will tell well in the production of eggs. Perhaps this is the best hen-house locality for securing eggs in winter which can be suggested to the frugal and judicious. Besides, the fowls are here free from many dangers, and safe from many enemies, to which they are exposed in a lower and more open situation.'

The three golden rules to be kept in view by all poultry-keepers, are: *cleanliness*, *warmth*, and *attention*. Without these, the inmates of the poultry-yard can never attain perfection, and, consequently, the breeder will derive only a part, not the whole, of the profit which would otherwise be gained. Every poultry-house should be well cleaned at least once a week, to free it from vermin, hurtful odours, &c. . In farms, and other places where a great stock of poultry is kept, a proper house, with separate accommodation for the different varieties, should be provided; this is a point, moreover, which is rarely attended to. The hen-house should have at least four compartments and a court-yard. The annexed sketch exhibits the requisite accommodation. *a a*, the court-yard; *b b*, for ducks and geese, the apartment for which is at *c*, with laying and hatching-nests, *d*; *g*, the roosting-house for hens and turkeys; *e*, the hatching-house; and *f*, the apartment for laying. Each compartment should be provided with a shutter door, which must be closed every night. If, through inattention, the hen-house should become *tainted*, the health of its inmates will be greatly endangered. A new site should be chosen, and another house erected; or if this be impracticable, the house should be well fumigated, and washed with hot lime-water. The floors should be paved with stone, brick, or tiles; a cheaper kind may be formed of lime, with smith's or common ashes, finely broken and well mixed, and laid on with a trowel.

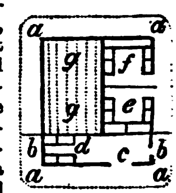

Fig. 5.

The laying-boxes require frequent washing with hot lime-water inside, to free them from vermin which greatly torment the sitting-hens. For the same purpose, poultry should always have a heap of dry sand or fine ashes laid under some covered place, or shady tree, near the yard, to dust themselves in; this being their resource for getting rid of the vermin with which they are annoyed.

The office of keeping and managing domestic fowls should be performed constantly by the same individual, as the voice and presence of a stranger scare them, and disturb the operations of the hen-house. To distribute food and drink at regular hours, to visit the nests, to remove eggs as soon as laid, and carry them to a cool place, to examine by candle-light what eggs are fecundated, and to place these under the hen, and mark the time, are among the daily duties to be performed by the keeper. When the hens lay in a secret corner or covert, the keeper may sometimes discover it by placing a few

grains of salt in the oviduct, which hurries on the process of laying, and causes the animal to retire to the spot anew.

The poultry-house should be built on a sloping piece of gravelly ground, well drained, and, if possible, at a spot which will afford shelter from sun and wind. The roof should be quite weather-tight, as poultry never thrive when exposed either to cold draughts or moisture. The interior should be at least six feet high, for the convenience of the person who cleans the house. The perches should be placed so that the fowls on the top row may not be immediately above those on the second, and so on; a hen-ladder must be provided, but this, like the roosts, should not be too high, as fowls are apt to injure themselves by flying from lofty perches. The floors should be strewn with sand, and should be swept clean every day: those sweepings will be found most useful for the garden. The door should be kept open in fine weather for the sake of ventilation; it should also have a hole at the bottom, with a sliding panel, that the hens may have access to their nests through the day.

Fig. 6 represents a section of a range of pens for the

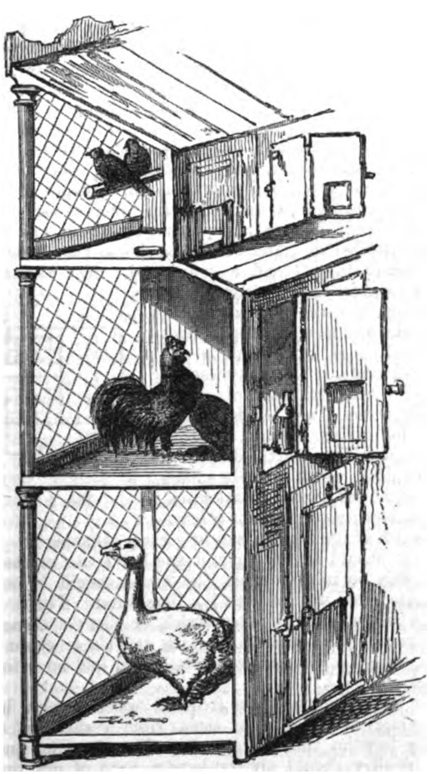

Fig. 6.—Poultry-pen.

exhibition of poultry of the various kinds, constructed on the principle of shewing all the animals of the same species under the same light, and the same conditions generally. The suite of ground-compartments is adapted for geese, ducks, turkeys, rabbits; the next stage is for gallinaceous fowls of the various breeds; and the upper stage is provided with a perch for pigeons, and might also be used for dwarf-fowls. It is a French design.

Feeding.—Most persons are doubtless aware that fowls swallow food without mastication. That process is rendered unnecessary by the provision of a *crop*, an organ which is somewhat similar to the first stomach of the cow, and in which the food from the gullet is macerated, and partly dissolved by secreted fluids. From the crop, the food passes downwards into a second small cavity, where it is partly acted on by a digestive juice; and, finally, it is transferred to the gizzard, or last stomach, which is furnished with muscular and cartilaginous linings of very great strength. In the gizzard, the partially softened food is triturated, and converted into a thin paste, fit to be received into the chyle-gut, and finally absorbed into the circulation. Such is the power of the gizzard in almost all kinds of poultry, that hollow globes of glass are reduced in it to fine powder in a few hours. The most rough and jagged bodies do no injury to the coats of the gizzard. Spallanzani even introduced a ball of lead, with twelve strong needles so fixed in it that their points projected a fourth of an inch from the surface, and the result was, that all the needles, with the exception of one or two, were ground down in a short time to the surface of the ball, while those left were reduced to mere stumps. It is remarkable that, to add to the triturating powers of the gizzard, fowls are gifted with the instinct of swallowing gravel with their food.

Fowls, when left to roam at large, pick up all sorts of seeds, grains, worms, larvæ of insects, or any other edible substances they can discover, either on the surface of the ground or by scraping. They also pick a little grass as a stomachic. The more that hens can be allowed to run about to gather their food, the better for their health and the pockets of their keeper. When secluded, and fed altogether in an artificial manner, their keep becomes expensive, and is, on the whole, seldom compensated by their produce. We have indeed great hesitation in advising any one to keep fowls who cannot inexpensively give them plenty of refuse from the table, or permit them to range in a field or lane in quest of what seems proper for their natural appetite. The very pleasure of ranging and scraping seems advantageous to them.

If kept in a court-yard or pen, and requiring altogether artificial feeding, their natural tastes should be consulted as far as conveniently practicable. They should be fed regularly, and with a miscellaneous kind of diet; allowed at all times access to clean water for drinking, and have earth, sand, or dust to scrape at pleasure and roll themselves in. A certain quantity of chalk or lime should also be scattered about for them to pick up, as that material is required by them in the production of eggs. Speaking on this subject, Professor Gregory of Aberdeen, in a letter to a friend, published in a newspaper, observes: 'As I suppose you keep poultry, I may tell you that it has been ascertained that, if you mix with their food a sufficient quantity of egg-shells or chalk, which they eat greedily, they will lay, other things being equal, twice or thrice as many eggs as before. A well-fed fowl is disposed to lay a vast number of eggs, but cannot do so without the materials for the shells, however nourishing in other respects her food may be; indeed, a fowl fed on food and water free from carbonate of lime, and not finding any in the soil, or in the shape of mortar, which they often eat off the walls, would lay no eggs at all, with the best will in the world.'

In a state of domestication, the hard food of which fowls seem most fond, are peas, barley, oats, &c.; and besides a proportion of these, they may be given crumbs of bread, lumps of boiled potatoes, not too cold, cabbage, turnips chopped small, &c. They are much pleased to pick a bone; the pickings warm them, and excite their laying propensities. If they can be supplied with caterpillars, worms, or maggots, the same end will be served. Any species of animal food, however, should be administered sparingly; and the staple articles of diet must always be of a vegetable nature. They should be fed three times a day. When wanted for the table, the quantity of food may be increased, and be more substantial; they should also be kept more within the coop,

and as quiet as possible. A fortnight's feeding in this way will bring a fowl of a good breed up to a plump condition.

Laying.—The ordinary productiveness of the hen is truly astonishing, as it usually lays, in the course of a year, 200 eggs, provided it be allowed to go at liberty, is well fed, and has a plentiful supply of water. Many instances have been known of hens laying 300 in a year. This is a singular provision in nature, and it would appear to have been intended peculiarly for the use of man, as the hen usually incubates only once in a year, although she will occasionally bring out two broods. Few hens are capable of hatching more than from twelve to fifteen eggs; so that, allowing they were all to sit twice a year, and bring out fifteen at a time, there would still be at least 170 spare eggs for the use of man. It is therefore evident that, in situations where hens can pick up their food, they must prove very profitable; for, supposing that the eggs of one fowl during the year were sold, without any of them being hatched, they would bring, if near a large city, on an average, 9d. per dozen, or 14s., and the hen herself would be worth 2s. at least. As the number of eggs which are annually brought out by a hen bear no proportion to the number which she lays, schemes—to be subsequently noticed—have been imagined to hatch all the eggs of a hen, and thus turn her produce to the greatest advantage; so that in place of twelve or fourteen chickens, upwards of 200 may be produced from the annual produce of a single fowl.

Hens will lay eggs which have received no impregnation, but from these, as a matter of course, no hatching can take place; they are equally good, however, for eating. When the chief object is to breed chickens, a cock should be allowed to walk with ten or twelve hens; but when eggs are principally required, the number of hens may be from fifteen to twenty. Endeavour to procure a cock of a good breed, not game, and let him be in his prime, which is at eighteen months to two years old. Cocks will last two years, after which they lose their liveliness of colours, and become languid, inactive, and mere consumers of food. It is fit, therefore, that younger cocks should then take their place in the poultry-yard. It is common to make choice of a young cock, by pitting one or two against each other, and selecting the most courageous, which is always sure to be the favourite of the yard.

Some remarks have been made on the colours of the best hens of the different varieties. As to other qualities, M. Parmentier recommends that they should be chosen of a middling size, robust constitution, large head, bright eyes, and pendent comb. Crowers should be rejected, and those that are of quarrelsome tempers, such hens being rarely good hatchers or layers. Old hens, or those above five years old, are of little use when added to a stock; and when the comb and claws are rough, it is a sign that they have ceased to lay.

If left to themselves, hens would produce, like some wild birds, two broods in the year. Early spring, and, after a cessation, the end of summer, are the two seasons in which they begin naturally to lay. In the depth of winter, under ordinary circumstances, hens very rarely lay eggs, though by artificial means they can be made to do so. If the temperature of the place where they are kept be raised by a stove, or otherwise, they will produce eggs. The fowls of the Irish peasantry, which are usually kept in the cabins of the owners, lay often in winter, in consequence of the warmth of their quarters; and there can be no doubt that warmth affords the most effective means of procuring new-laid eggs in winter, though stimulating food may aid in producing the same result. The fecundity of hens varies considerably. Some lay but once in three days, others every second day, and others every day. In order to induce laying, each hen should have its own nest, made with soft straw or heather, and furnished with a piece of chalk as a decoy or *nest-egg*. The signs which indicate when a hen is about to lay are well known. She cackles frequently, walks restlessly about, and shews a brighter redness in her comb and wattles. After the process of laying is over, she utters a series of loud and peculiar notes, to which the other fowls usually respond. Shortly after the egg is laid, it should be removed, for the heat of the hen soon corrupts it. When the eggs are taken away by the poultry-keeper, they should immediately be laid in a cool and dry place. If allowed to absorb damp, they soon spoil; indeed one drop of water upon the shell quickly taints the whole egg.

Various methods have been tried to prevent the absorption of air through the shell, and preserve the freshness of the eggs. A not uncommon plan is to keep them secluded from the air in bran, rye, or ashes, which may do very well where the eggs are to be kept in this way till eaten, but is utterly useless if quantities of them have to be sent to market. We beg to offer a plain piece of advice to cottagers on this subject, which, if properly acted on, will give them the means of at all times commanding the highest price for *fresh eggs*, although situated a hundred miles or more from the place of sale. *Smear all your eggs with a bit of fresh butter the moment you get hold of them.* Do not load the shell with grease, but merely give a light varnish. The butter must be good. By this simple process of smearing, which does not taint the interior in the slightest degree, the egg is as fresh at the breakfast-table, and possesses all the delicious milkiness when three months old, as if just newly laid. Scarcely anything is more common than to hear complaints of the difficulty of getting fresh eggs, and all a result of the sheer negligence of fowl-keepers. By the plan we mention, there need rarely be such a thing as a bad egg heard of. Dipping in lime-water and some other processes are said to be equally effectual.

Hatching.—When eggs are to be hatched, it is necessary to pay attention to the choice of proper ones for the purpose. The company of the male bird renders the hen productive of fecundated eggs; and, as already noticed, it is only eggs of this kind that are available for producing young. The eggs must also be fresh; from the time they are laid, they should lie aside in a cool place. It is said to be possible to ascertain, from the appearance of the egg, whether the forthcoming progeny is to be male or female. When eggs are left to be brought forth by the hen, a certain number are placed under her in the nest, when she is in the full inclination to sit. From nine to twelve eggs are placed, according to the extent of the breast and wings; and the time required for hatching is about twenty-one days. Sometimes a hen will desert her eggs, a circumstance which may occasionally be traced to an uncomfortable condition of the skin, caused by vermin or want of cleanliness; and this affords a strong reason for keeping the hen-house clean, and giving the animals the means of purifying their feathers. Occasionally, the hen is vicious, or, in short, a bad sitter, and experience in pitching on the best hatching-hen is the only remedy. Sometimes a hen will break her eggs with her feet; and in such cases the broken eggs must be removed as soon as observed, otherwise she may eat them, and from that be tempted to break and eat the sound ones, and thus spoil the whole.

It has generally been found that hens which are the best layers are the worst sitters. Those best adapted have short legs, a broad body, large wings, well furnished with feathers, their nails and spurs not too long or sharp. The desire to sit is made known by a particular sort of clucking note, or, as it is termed in Scotland, *kloking;* and a feverish state ensues, in which the natural heat of the hen's body is very much increased. The inclination, or, as physiologists term it, the *storge*, soon becomes a strong and ungovernable passion. The hen flutters about, hangs her wings,

bristles up her feathers, searches everywhere for eggs to sit upon; and if she finds any, whether laid by herself or others, she immediately seats herself upon them, and continues the incubation.

With a proper provision of food at hand, warmth, quiet, and dryness, a good hatching-hen will give little trouble, and in due time the brood will come forth; one or two eggs may perhaps remain unhatched or addled, but their loss is of little consequence. As soon as the hen hears the chirp of her young, she has a tendency to walk off with them, leaving the unhatched eggs to their fate. It is therefore advisable to watch the birth of the chicks, and to remove each as soon as it becomes dry, which may be in a few hours afterwards. By this means the hen will sit to hatch the whole; yet she should not be wearied by too long sitting. If all the eggs are not hatched at the end of twelve or fifteen hours after the first chick makes its appearance, in all probability they are addled, and may be abandoned. The chicks must be kept in a warm place during the first day, and at night restored to the mother, who now assumes her maternal duties. The food given to the young chicks should be split grits, which they require no teaching to pick up; afterwards the ordinary food of the poultry-yard, or what the mother discovers for their use, is sufficient. Some give the yolks of hard-boiled eggs or curd, when a nourishing diet seems advisable. The extreme solicitude of the hen for her young, or the brood which may be imposed upon her, is well known. She leads them about in quest of food, defends them by violent gesticulations and the weapons which nature has given her, calls them around her by a peculiar low clucking cry, and gathers them carefully under her wings, to shelter them from danger or to keep them warm at night. This maternal care is bestowed as long as the chickens require her assistance; as soon as they can shift for themselves, the mutual attachment ceases, and all knowledge of each other is very speedily lost. The young now go to roost, and the mother again begins to lay. Young hens, usually called pullets, begin to lay early in the spring after they are hatched.

Artificial Hatching.—As heat is all that is necessary to develop the chick in the egg, eggs may be hatched artificially, without the intervention of the hen. The art has long been practised in Egypt, and has since been adopted in many other quarters, but with indifferent success. In the variable and moist climate of Great Britain, at least, there is little chance of Eccaleobions, or Patent Incubators, ever superseding, to any great extent, the office of the brooding-hen.

Capons.—The best modes of fattening fowls for the table have been adverted to. The process of converting chickens into capons, however, ought also to be noticed here. By removing the reproductive and oviparous organs from the male and hen chickens respectively, a great change is produced in them as regards voice and habits, and they can be made remarkably fat for the table. Capons are chiefly reared in Sussex, Essex, and one or two other counties around London. They can be trained to watch chickens, hatch eggs, and do many useful offices of the poultry-yard. Upon the whole, however, the special benefit derived from rearing capons does not counterbalance the trouble which they give and the danger of the primary operation; for an account of which, as practised in different countries, see Dickson on Poultry.

Diseases.—Chickens are liable to various diseases, demanding attention from the poultry-keeper. The *pip* is the most common; it consists of a catarrhal thickening of the membrane of the tongue, causing a dangerous and obvious obstruction to respiration. It may be cured in most cases by throwing the fowl on its back, holding open the beak, and scraping or peeling off the membrane with a needle or the nail. The part may be wetted with salt or vinegar afterwards, and a little fresh butter pushed over the throat. Dr Bechstein recommends giving a mixture of butter, pepper, garlic, and horse-raddish, as an internal remedy. But the operation is most effective. *Thirst* sometimes attacks fowls like a fever, and often arises simply from dry food, though more frequently symptomatic of indigestion or some internal and deep-seated derangement. Careful attention to diet is the first and great point in all such cases. If *constipation* appear to be present, bread soaked in warm milk, boiled carrots or cabbages, earth-worms, chopped suet, or hot potatoes with dripping, will be found useful. A clyster of sweet oil should be tried in severe cases. Where a tonic seems to be required, a little iron-rust may be mixed with the food, and will generally relieve atrophy or loss of flesh. Where diarrhœa or scouring is observed, iron or alum may be given in small quantities. There is also a species of influenza called the *roup*, which is often epidemical in the poultry-yard, and causes much havoc among the young birds. The eyes become swollen, a discharge comes from the nostrils, and the fowl gapes continually, shewing much difficulty of breathing. Some observers have ascribed this complaint to worms in the windpipe, and have recommended their extraction by an operation; but warmth, cleanliness, soft food, and such laxatives as sulphur, with frequent ablutions of the eyes and nostrils, are more likely, perhaps, to do good, and are not attended with danger. Where general fever has been observed in fowls, the use of a little nitre has been found very advantageous. Saffron is another remedy very often employed in relieving the symptoms of sickness in fowls.

Many of these remarks will apply equally well to the diseases of geese and the other species of domestic poultry yet to be noticed; and this subject, therefore, need not again be adverted to in detail.

Turkeys.

The turkey, like the common fowl, has been included by naturalists in the *Gallinaceous* family of birds, and possesses the main characteristics common to the whole. It is a native of the woods of North America, and is certainly one of the most valuable fowls which have been naturalised in this country, but is very difficult to rear. The turkey-hen lays from fifteen to twenty eggs, and then sits upon them. She will bring out two broods in a year. The eggs are of a pale yellowish-white colour, finely streaked and spotted with reddish-yellow. They are a most delicious food, much more delicate in their flavour than those of the common hen. In England or Scotland, however, the eggs are comparatively seldom to be met with for sale, being deemed too valuable to be used as food. In Ireland, they are to be got in the markets in great abundance, especially in the midland counties, where we have bought them at ninepence per dozen. In that country, when the hen has laid about half-a-dozen eggs, they afterwards take away one daily, by which means the hens are induced to produce a greater number of eggs than otherwise. This they assist by means of stimulating food, such as hemp-seed and buckwheat. There is an interval of a day between the laying of each egg. It is said that the first two eggs which she lays are unfruitful. A turkey-hen can seldom hatch more than from sixteen to eighteen eggs. The time of incubation varies from twenty-seven to twenty-eight days, at which time the young begin to pierce their shelly prison, and emerge from it.

General Treatment.—When turkey-chicks first come forth, they are extremely weak, and much assiduous care is necessary to rear them. The first thing to be attended to is, to remove them to a situation where they are not exposed to the sun's rays, which at first are too powerful for them. A woody place is the most suitable to their natural habits. Nothing is so destructive to them as rain, from which they must be protected. When young turkeys accidentally get wet, they should be brought

into a house, carefully dried by applying soft towels to them, and then placed near a fire, and fed upon bread which has been mixed with a small proportion of ground pepper or ginger. It should be made up in the form of small peas. If the bread is too dry for this purpose, it may be moistened with a little sweet milk. Should the turkey-poults refuse to eat it, a few of these pellets may be forced down their throats. Even heavy dews prove destructive to them, and frost is no less injurious in its effects. These must, therefore, be most carefully guarded against when the hens incubate in March or early in April. Dry and sandy situations are most congenial for breeding turkeys, and especially elevated situations where large woods are contiguous. A single male turkey is sufficient for twelve or sixteen females, although the former number is probably the safest, to prevent sterility in the eggs, which is frequently the case with those of turkeys. Eggs should never be intrusted to the care of a female until she is at least two years of age, and they may be kept for the purpose of incubation till they reach their tenth year. The largest and strongest hens should always be kept for this purpose. During the time the hen is sitting, it becomes necessary to place food near her; otherwise, from her assiduity, she may be starved to death, as turkey-hens seldom move from their nest during the whole time of incubation.

Where farmers rear turkeys in great numbers, they do not indulge the hen by allowing her to sit as soon as she has done laying, but keep them from her until all the other hens have ceased to lay, as it is of consequence that they should all be hatched about one time. When hens are unhappy during this interval, they may be indulged with hens' eggs. When they have all ceased to lay, each of them is provided with a nest ranged close to the wall, in a barn or other convenient place, and each is supplied with from sixteen to twenty of her own eggs. The windows and doors are then closed, and only opened once in the twenty-four hours for the admission of air, and for the purpose of feeding the hens. They are taken off their nests, fed and replaced, and again shut up. On the twenty-sixth day, the person who is intrusted with the management of the birds examines all the eggs, and removes those that are addled; feeds the hens, and does not again disturb them till the poults have emerged from their shells, and have become perfectly dry, from the heat of the parent bird: to be subjected to cold at this time would certainly kill them. When the young birds are thoroughly dried, two of the broods are joined together, and the care of them intrusted to a single hen; and those which have been deprived of their offspring are again placed on hens' or ducks' eggs, and subjected a second time to the tedious operation of incubation, in which case it is not unusual for them to bring out thirty eggs. We cannot recommend this practice in point of humanity; for the poor hens, when they have accomplished their second sitting, are literally reduced to skin and bone, and frequently so weak as hardly to be able to walk.

As before hinted at, great care should be taken of the young turkey-poults; besides warmth, proper food and shade, the nearer they are to a pure running stream the better, as they drink a great deal; and nothing is of greater importance to their being successfully reared than fresh drink. They must be also carefully protected from strong gusts of wind, and on the slightest appearance of a thunder-storm, should be immediately taken into a house. They should get no food for twenty-four hours after they leave the egg. Their first food should be hard-boiled eggs finely chopped, and mixed with crumbs of bread. Curd is also an excellent food for them. When they are about a week old, boiled peas and minced scallions are given to them. If eggs are continued, the shells should be minced down with their food, to assist digestion, or some very coarse sand or minute pebbles. They should be fed thrice a day; and as they get older, a mixture of lettuce-milk will be found beneficial, together with minced nettles. Barley boiled in milk is another excellent food at this period, and then oats boiled in milk. In short, the constitution of young turkeys requires at all ages every kind of stimulating food. When about three weeks old, their meat should consist of a mixture of minced lettuce, nettles, curdled milk, hard-boiled yolks of eggs, bran, and dried chamomile; but when all these cannot be readily obtained, part of them must be used. Fennel and wild endive, with all plants which are of a tonic character, may be safely given to them. Too much lettuce, however, has been found to be injurious. When poults are about a month old, they should be turned out, along with the parent bird, into the fields or plantations, where they will find sufficient food for themselves. Grass, worms, all kinds of insects and snails, are their favourite food, and nature dictates to them such vegetables as are conducive to their general health. As their feet are at first very tender, and subject to inflammation from the pricking of nettles and thistles, they ought to be rubbed with spirits, which has the effect of hardening the skin, and fortifying them against these plants.

The glandulous fleshy parts and barbles of their heads begin to develop when they are from six weeks to two months old. This is a critical period with the poults, and unusual care must be bestowed on them, as they now become weak, and often sickly. A little brine mixed with their food will be found very beneficial, or spirits much diluted with water. A paste made of fennel, pepper, hemp-seed, and parsley, has been found an excellent remedy when afflicted with an inflammation in the wattles, to which they are liable when growing. They are very subject to this if the weather happens to be broken and changeable at the time these tubercles are growing. These parts swell and grow very red, which frequently proves fatal to them. If, therefore, such be the state of the weather at this critical period, the paste above recommended should be given although they are perfectly healthy, which will be found an excellent preventive. When the inflammation becomes very great, recourse is often had to bleeding in the axillary vein, which frequently has the effect of recovering them.

Soon after the turkey-poults have acquired their first feathers, they are liable to a disease which is very fatal to them, if not attended to. This distemper produces great debility, and the birds appear languid and drooping, and almost totally neglect their food. Their tail and wing-feathers assume a whitish appearance, and their plumage has a bristled aspect. This is occasioned by a disease in two or three of the rump-feathers. On examination, the tubes of these will be found filled with blood. The only remedy for this disease is to pluck them out, when the bird will speedily acquire its wonted health and spirits.

In fattening turkeys for the table, various methods are resorted to. Some feed them on barley-meal mixed with skim-milk, and confine them to a coop during this time; others merely confine them to a house; while a third class allow them to run quite at liberty; which latter practice, from the experience of those on whose judgment we can most rely, is by far the best method. Care should, however, be taken to feed them abundantly before they are allowed to range about in the morning, and a meal should also be prepared for them at midday, to which they will generally repair homewards of their own accord. They should be fed at night, before roosting, with oatmeal and skim-milk; and a day or two previous to their being killed, they should get oats exclusively. We have found from experience that when turkeys are purchased for the table, and cooped up, they will never increase in bulk, however plentifully they may be supplied with food and fresh water, but, on the contrary, are very liable to lose flesh. When feeding them for use, a change of food will also be found

beneficial. Boiled carrots and Swedish turnips, or potatoes mixed with a little barley or oat meal, will be greedily taken by them. A cruel method is practised, chiefly on the continent, to render turkeys very fat, which is termed cramming. This is done by forming a paste of crumbs of bread, flour, minced suet, and sweet milk, or even cream, into small balls about the bulk of a marble, which is passed over the throat after full voluntary meals. The liver of those turkeys, prepared in a peculiar way, forms the *pâté de foie gras* of epicures.

Pea-fowl.

The peacock, also one of the gallinaceous tribe of birds, came originally, it is said, from India, and was well known to the ancient Greeks and Romans, who introduced it into their mythology. The great beauty of its tail, so ample in extent and so rich in colours, rendered it indeed not unworthy of such preferment.

One peacock is usually kept with three or four hens. The female is extremely fastidious about a spot to lay in, and generally leaves any artificial nest for the grass of some neighbouring coppice, where she lays under the branches of a shrub, in a well-concealed situation. One reason for this is the propensity of the cock to break the eggs if he discover them. When the eggs of the peahen are gathered in sufficient numbers, whether from a natural or artificial nest, it is a common practice to place them under a common hen, which hatches them in thirty days, and makes an excellent stepmother to the young chicks. These are very tender at first, but soon grow vigorous, even in a chilly climate. Barley-meal paste, mixed with cheese or curd prepared from milk, with alum, ants' eggs, meal-worms, and hard-boiled egg, are among the common articles of diet given to the young. The grown-up pea-fowl feeds on boiled barley or other common grains, and is a dangerous visitor of corn or wheat fields and gardens. On the other hand, they are voraciously fond of such creatures as frogs, lizards, and the like, and keep grounds clear of such annoyances. In moulting-time, it is requisite to be more careful of these fowls than at other times, and to give them good grain, with a little honey and fresh water. Though the tongues and livers of peacocks were ranked among the dainties of the Roman epicures, the bird is rarely killed for table now a days. Yet it always bears a high price, being one of the most beautiful of the feathered race, and an object on which the eye ever delights to dwell, though its screaming note by no means gives a corresponding pleasure to the ear.

The Guinea-fowl.

This stranger is found native in Africa, as its name indicates, and it also exists in an indigenous state in South America. The Guinea-fowl (*Numidia meleagris*) is about the size of the common hen, and the male differs very little in appearance from the female. Three species exist in considerable numbers in Europe—namely, the crested, the mitred, and Egyptian varieties. A very beautiful sort is marked by a pure white tint of body, but the most familiar hues are dark-gray and black. The bird is less tame than other common poultry, and prefers to live in a half-wild condition in its native regions, perching and living on trees like undomesticated birds. It is a spirited creature, and will battle even with the turkey. Guinea-hens require great attention at the time of laying, making their nests by preference in corners of the woods. Their eggs are small, but much esteemed; and the common hen is usually made to rear their broods. In the market, guinea-fowls always bear a high price, both on account of their flesh, which is of a good quality, and because they form a very pretty variety of the poultry stock. Their food is grain, of the various kinds given to ordinary barn-door fowls, with which they assimilate closely in habits. On the whole, they may be said to be kept more from curiosity than for profit.

The Goose.

The goose differs in many respects from the fowls already noticed, being aquatic in its habits. It is marked by a flat bill and webbed feet, characters also possessed by the duck and swan, which, in conjunction with the goose, may be held as forming a distinct family (*Anatidæ*) of the feathered aquatic tribes.

Our common tame goose is the wild species domesticated, known to naturalists by the name of the fen or stubble goose. Where people have a right of common, or live in the vicinity of marshy heaths, the breeding and rearing of geese will prove very profitable, for in such situations they are kept at a trifling expense; they are very hardy, and live to a great age. If properly kept, and fed regularly, although sparingly, they will lay upwards of 100 eggs yearly. If these are set under large hens, each having half-a-dozen, with the assistance of the goose herself, they may be nearly all hatched. For the first three or four days, they must be kept warm and dry, and fed on barley-meal or oatmeal mixed with milk, if it is easily procured; if not, let these ingredients be mixed with water. They will begin to grow in about a week. For a week or two the goslings should not be turned out till late in the morning, and should always be taken in early in the evening. In Ireland, the tenantry depend much on the breeding of these birds and turkeys to pay their rent; and with those who are industrious and favourably situated for rearing geese, they even do more in many instances. In the early part of the year, they are allowed to feed on grass, on heaths, meadows, commons, and roadsides; and as most of the peasantry have small bits of corn-land of their own, the geese are turned out on the stubble to pluck what grass is left; and they also fatten upon it, and improve the flavour of their flesh.

Although water be the natural element of geese, yet it is a curious fact that they feed much faster in situations remote from rivers and streams. To fatten geese, it is necessary to give them a little corn daily, with the addition of some raw Swedish turnips, carrots, mangel-wurzel leaves, lucerne, tares, cabbage leaves, and lettuces. They should not be allowed to run at large when they are fattening, as they do not acquire flesh nearly so fast when allowed to take much exercise. Therefore those who can only afford to bring up a goose or two, should confine them in a crib or some such place about the beginning of July, and feed them upon the ingredients above recommended, with a daily supply of clean water for drink. If, on the contrary, from a dozen to twenty are kept, a large pen of from fifteen to twenty feet square must be made, and well covered with straw in the bottom, and a covered house in a corner for protection against the sun and rain when required, because exposure to either of these is not good. It will be observed that about noon, if geese are at liberty, they will seek some shady spot, to avoid the influence of the sun; and when confined in small places, they have not sufficient room to flap their wings and dry themselves after being wetted; nor have they room to move about so as to keep themselves warm. There should be three troughs in the pen, one for dry oats, another for vegetables—which ought always to be cut down—and a third for clean water, of which they must always have a plentiful supply. It must be remembered that the riper the cabbages and lettuces with which they are supplied, the better. In the neighbourhood of large towns, the most profitable way of disposing of geese is in a dead state; as nearly the same sum can be obtained for them as if they were alive; and then you have the feathers, which are valuable, and may be sold to much advantage by themselves when you have collected a stone-weight or more.

Geese are kept in vast quantities in the fens of Lincolnshire, several persons there having as many as 1000 breeders. They are bred for the sake of their quills

and feathers, as well as for their carcass; it is therefore customary to strip them partially of the fine downy feathers, and leave them to grow afresh, and also to take quills from their wings—both practices barbarous in the extreme, however they may be attempted to be justified. Geese breed in general only once a year, but if well kept, they sometimes hatch twice in a season. The best method for promoting this is to feed them with corn, barley, malt, fresh grains, and, as a stimulant, they should get a mixture of pollard and ale. During their sitting, each bird has a space allotted to it, in rows of wicker-pens placed one above another, and the goose-herd who has the care of them, drives the whole flock to water thrice a day, and bringing them back to their habitation, places every bird—without missing one—in its own nest. One gander is generally put to five geese. The time of incubation varies from twenty-seven to thirty days. The goose begins to lay in March, but the time of the month depends upon the state of the atmosphere. When goslings are first allowed to go at large with their dam, every plant of hemlock which grows within the extent of their range should be pulled up, as they are very apt to eat it, and it generally proves fatal to them. Nightshade is also equally pernicious to them, and they have been known to be poisoned by cropping the sprigs of the yew-tree.

Ducks.

Ducks are easily kept, particularly near ponds or streams of water. In such situations, even the poorest families may have half-a-dozen of them running about without the least inconvenience. In keeping them in a domestic state, one drake is usually put to half-a-dozen ducks. The ducks begin to lay in February; their time of laying being either at night or early in the morning. They are extremely apt to deposit their eggs in some sequestered spot, and to conceal them with leaves or straw. From eleven to fifteen eggs is the number which a duck can properly cover. The time of incubation is about thirty-one days. The place where they incubate should be as quiet and retired as possible; and if they have liberty, they will give no trouble whatever in feeding, as the duck, when she feels the call of hunger, covers her eggs carefully up, and seeks food for herself, either by going to the streams or ditches in her neighbourhood, or, if such are not at hand, she will come to the cottage and intimate her wants by her quacking. When the young are hatched, they should be left to the care of the duck, which will lead them forth in due time; and when she does so, prepare a coop for them, which should be placed on short grass, if the weather is mild; and if cold or stormy, they should be kept under cover. The future strength of the brood will depend much upon the care that is taken of them for the first three or four weeks after they have emerged from the shell. Ducklings will begin to wash themselves the first day after they are hatched, if they find water at hand; therefore a flat dish filled with that element should be always within their reach. Many persons are in the practice of clipping the tail, and the down from beneath it, in ducklings, if the weather is wet during the first weeks of their existence. This is to prevent them from draggling themselves, which has a tendency to produce intestinal diseases. From a fortnight to three weeks is all that is necessary to confine them to the coop.

The first thing on which ducklings are fed is a mixture of barley, peas, or oat meal, and water. They may afterwards be fed upon a mixture of buckwheat, and any of the above-named meals. The greatest attention must be paid to keeping their bed warm and dry; and with young ducks, a frequent change of straw is absolutely necessary, as their beds soon get dirty, wet, and fetid.

Ducks are not such attentive guardians of their young as hens, and therefore it is a common practice to place duck-eggs under a sitting hen, and leave her to hatch them as her own progeny. When the young ducks so hatched make their appearance, the hen does not appear aware of the imposition, but takes at once to her duties with all a mother's fondness. The natural desire of the ducklings to plunge into water and swim away from the shore vexes her, but she watches for their return, and does all in her power to provide the means of subsistence. She scrapes for them, which a duck would not; she shelters them under her dry and warm bosom and wings, and altogether makes a better nurse than their own proper parent.

In feeding ducks for use, peas and oat meal are to be preferred. It is said that barley-meal renders their flesh soft and insipid. Bruised oats should be given to them freely for some weeks before they are killed, which renders their flesh solid and well tasted; and the same general principles recommended in the feeding of geese should be kept in view. It has been found that the offal of butchers' shops feeds ducks quickly, and that this does not impair the flavour of their flesh. In very many instances, ducks are reared in situations where there are no pools of clean water for them to dabble in, and the poor animals are compelled to grub with their bills in all sorts of nauseous puddles, which of course makes their flesh rank and offensive. They should in all cases have a pool of clean water to swim in, and are best reared near a natural meadow, lake, or pond, where they can search for their appropriate food.

Those who have paid much attention to the management of domestic poultry, assert that geese and ducks should be kept apart from other fowls. The former should have their houses ranged along the banks of a piece of water with a fence, and sufficiently extensive for walks in front, with doors for their access to the water, which can be closed at pleasure.

Swans.

Swans are generally kept for ornament rather than use. The flesh, even of the young, is black, hard, and rank, while that of the old is too tough for mastication. The eggs also are not peculiarly palatable; and there is little inducement to rear them, in short, if mere pecuniary advantage be looked to, excepting on the score of the skin, feathers, and down, which are articles of considerable value. At the same time, if the swan be not a productive bird, few animated objects can be compared with it as regards ornament. Its great size, snow-white plumage, and graceful form, render it a most attractive spectacle upon the bosom of a pool or lake. It is a hardy, long-lived fowl, and associates in pairs. The food of the swan consists usually of seeds, roots, and plants, rendered succulent by water. When fed in a barn-yard, it seldom thrives, being more decidedly aquatic in its habits than ducks or geese. From the colour of the European swan being so uniformly white, a black swan used once to be proverbially spoken of as an impossibility; but black swans occur abundantly in Australia, from whence they are now frequently brought, as curiosities for the pleasure-ponds of the wealthy.

Pigeons.

Pigeons are among the most ornamental and useful appendages of a rural dwelling. If permitted to fly abroad to seek their food, little expense will be incurred for their keep, while the value of their young will be of some importance to cottagers. The pigeon has a great power of flight, and will go to a distance of many miles in quest of the means of subsistence; but wherever it may fly, it never fails to return home. The leading features of the district around its habitation appear to be impressed on its memory; and flying at a great height, and with a wonderful power of vision, it sees the well-remembered landmarks, and directs its path homeward. This habit of seeking for the place at which it was reared, makes it difficult to keep pigeons in any new home; the best plan of inducing them to settle in

a new abode is to clip one wing, which prevents their flying, and keep them in a cot near the ground till they get accustomed to the place.

Many persons keep their pigeons in the space between the garret and roof of their dwelling-house, with holes at which they go out and in; and this arrangement answers very well, for the animal's lodging must be dry and comfortable. A more regular plan is to furnish them with a properly constructed dove-cot, aloof from any building. The cot should consist of a substantial wooden box, with a sloping roof, and divided interiorly by partitions into as many cells as pairs are to be kept, for each pair requires a distinct cell. Each compartment should be twelve inches deep from front to back, and sixteen inches broad; the entrance-hole should not be opposite the centre of the cell, but at a side, so that the pigeons may build their nest a little out of sight. In front of each cell there should be a slip of wood to rest and coo upon; but as different pairs incessantly quarrel about the right of walking on these slips, and are apt to fight for the possession of cells, it is best to separate the slips with upright partitions; and it would be an improvement to have two or three small cots instead of one large one. The cot, of whatever size or form, should be elevated on a wall facing the south-east, or otherwise placed at such a height as will be out of the reach of cats and other vermin. The cot should be painted white, as the pigeon is attracted by that colour. Gravel should be strewed on the ground in front of the dove-cot, the birds being fond of picking it; and a little straw or hay is necessary for the nests. Cleanliness is indispensable to the health of the birds, and a scouring out of the cot should therefore take place regularly. The quantity of dung produced in the nests is very great, and its removal to the compost heap will amply repay the trouble of cleaning.

In commencing to keep pigeons, a pair or two should be procured which have not flown, and they should be shut up for a time, and well fed. Their chief food is grain, and the kind which they prefer to all others is dried tares. Small horse-beans are another favourite article of diet, and very nutritious to them. Wheat, barley, oats, and peas, with rape, hemp, and canary seeds, are also prized by them, but should not be made constant articles of food under any circumstances.

The house-dove, or common pigeon, as is well known, begins to breed about the age of nine months, and breeds every month. During breeding-time, they associate in pairs, and pay court to each other with their bills; the female lays two eggs, and the young ones that are produced are for the most part a male and female. When the eggs are laid, the female, in the space of fifteen days, not including the three days during which she is employed in laying, continues to hatch, relieved at intervals by the male. From three or four o'clock in the evening, till nine the next day, the female continues to sit; she is then relieved by the male, who takes his place from ten till three, while his mate is feeding abroad. In this manner they sit alternately till the young come out. Kept with ordinary care, a pair will give to the breeder nine pairs or so in a year, and will continue to do this for four years.

With regard to the best breeds of the common domesticated pigeon, it is difficult to give any useful instructions. They have been cultivated to a great extent, and many distinct varieties have been formed, but the differences rest chiefly in colours, and the special value of each lies in the taste of the *fancier*. The leading varieties of fancy-pigeons are known by the names of the English Pouter, the Dutch Cropper, the Horseman, the Unleper, the Dragoon, the Tumbler, the Leghorn and Spanish Runt, the Trumpeter, the Nun, the Fan-tail, and the Capuchin. The peculiarities of some of these breeds are very odd. The English pouter, depicted in the frontispiece, possesses the remarkable property of blowing out its breast or crop to such an extent, that it rises to a level with its beak, and the bird appears to look over the top of an inflated bladder.

Carrier-pigeons.—Pigeons have been put to the remarkable purpose of acting as carriers of letters or other light objects. A particular species, larger than common, is trained for the purpose, and in some countries the rearing of them forms a lucrative employment. The instinct which has rendered the carrier-pigeon so serviceable, is the strong desire manifested by all pigeons to return to the place of their ordinary residence; and man has adopted various precautionary measures in order to make its return on particular occasions more certain. A male and female are usually kept together, and treated well; and one of these, when taken elsewhere, is supposed to have the greater inducement to come back. It is even considered necessary by some that the bird should have left eggs in the process of incubation, or unfledged young ones, at home, in order to make the return certain; but probably these are superfluous precautions. It is obvious that the carrier-pigeon can only be put to use in conformity with some contemplated plan, for which the proper preparations have been made. It must have been taken from a place to which it is wished that it should return, and it must, at the moment when its services are wanted, be temporarily at the place from which the intelligence is to be conveyed. It is usually taken to that place hoodwinked, or in a covered basket: the instinct by which it finds its way back upon its own wings must of course be independent of all knowledge of the intermediate localities. When the moment for employing it has arrived, the individual requiring its services writes a small billet upon thin paper, which is placed lengthwise under the wing, and fastened by a pin to one of the feathers, with some precautions to prevent the pin from pricking, and the paper from filling with air. On being released, the carrier ascends to a great height, takes one or two turns in the air, and then commences its forward career, at the rate of about forty miles an hour.

CAGE-BIRDS.

The birds usually domesticated in cages in Britain are canaries, siskins, goldfinches, bullfinches, larks, linnets, thrushes, blackbirds, starlings, and parrots. The only means by which these or any other species of birds can be reared and preserved in a healthy condition, is to accommodate each as far as possible with the food, space for exercise, and other conveniences which the animal would enjoy in a state of nature. The most difficult thing to afford is space: where a room or aviary can be fitted up with all requisite accommodations—perches to resemble trees and branches, grass, moss, and other plants, patches of gravel or sand, secluded places for nests, a trough of clear water, &c.—the birds will thrive, breed, and be cheerful; but such accommodations can rarely be afforded, unless in the mansions of the great; and the aviary, for the most part, is only a tiny cage, more or less ornamental, formed of wood and wires.

Placed in this state of confinement, no birds can possibly exist unless great care is bestowed in furnishing them with food and fresh water daily, keeping their habitation very clean, and placing them in a cheerful situation in a parlour, where they can enjoy the light.

The food of cage-birds is very various. 1. Canaries, goldfinches, and siskins, live only on seeds; 2. quails, larks, chaffinches, and bullfinches, feed on both seeds and insects; 3. nightingales, redbreasts, thrushes, and blackbirds, take berries and insects. Referring to these classes of birds, Bechstein observes: 'Experience teaches me that a mixture of crushed canary, hemp,

and rape seed, is the favourite food of canaries; goldfinches and siskins prefer poppy-seed, and sometimes a little crushed hemp-seed; linnets and bullfinches like the rape-seed alone. It is better to soak it for the young chaffinches, bullfinches, and others: in order to do this, as much rape-seed as is wanted should be put into a jar, covered with water, and placed in a moderate heat, in winter near the fire, in summer in the sun. If this is done in the morning, after feeding the birds, the soaked seed will do for the next morning. All of them ought to have green food besides, as chickweed, cabbage-leaves, lettuce, endive, and water-cresses. Sand should be put in the bottom of the cages, as it seems necessary for digestion.

'Amongst those of the second class, the quails like cheese and the crumbs of bread; the lark, barley-meal, with cabbage, chopped cress, poppy-seed mixed with bread-crumbs, and in winter, oats; the chaffinches, rape-seed, and sometimes, in summer, a little crushed hemp-seed. Too much hemp-seed, however, is hurtful to birds, and should only be given as a delicacy now and then, for when they eat too much of it they become asthmatic, blind, and generally die of consumption. Yellow-hammers like the same food as the larks, without the vegetables; the tits like hemp-seed, pine-seed, bacon, meat, suet, bread, walnuts, almonds, and filberts.' The same author proceeds to describe two kinds of paste, simple and cheap, and which may be termed a universal food for birds.

'To make the first paste, take a white loaf which is well baked and stale, put it into fresh water, and leave it there until quite soaked through, then squeeze out the water, and pour boiled milk over the loaf, adding about two-thirds of barley-meal with the bran well sifted out, or, what is still better, wheat-meal; but as this is dearer, it may be done without.

'For the second paste, grate a carrot very nicely (this root may be kept a whole year if buried in sand), then soak a small white loaf in fresh water, press the water out, and put it and the grated carrot into an earthen pan, add two handfuls of barley or wheat meal, and mix the whole well together with a pestle.

'These pastes should be made fresh every morning, as they soon become sour, particularly the first, and consequently hurtful. For this purpose, I have a feeding-trough, round which there is room enough for half my birds. It is better to have it made of earthenware, stone, or delf ware, rather than of wood, as being more easily cleaned, and not so likely to cause the food to become stale.'

Canaries are the chief pets of the parlour, and the method of treating them requires to be given at some length. Being originally from a warm climate, they are tender, and must be kept in rooms of an agreeable temperature; if exposed to cold either in rooms or the open air, they pine and die. In dry weather in summer, their cage should be hung in the open air, or at least in the sunshine. If the apartment is kept too hot, they will moult at an improper season, and this must be avoided. Only one male should be allowed in a cage. Females for breeding are the better for having a large cage, as it affords them space for exercise. The greatest care must be taken to clean the cage, of whatever dimensions, and to scatter a little fine sand on the bottom of it. Each should be provided with three cross-sticks as perches; a small glass-trough for water fixed outside, at the extremity of one of the sticks. The water must be changed daily, or even more frequently.

Some persons, from mistaken kindness, offer pieces of rich cake and other inappropriate food to canaries, and the little creatures being fond of these things, they do themselves a great injury by eating of them.

The breeding of canaries requires additional accommodations. The breeder must have a large cage, into which the pair of birds is put about the middle of April. At the upper part of the cage, at one end, boxes for the nests are placed, with holes to go out and in by; and in the centre of the cage, near a perch, a net-work bag is hung filled with cotton, wool, moss, hair, and other soft materials, for the birds to use for their nests. The female only builds; and in about ten days after pairing, she lays the first egg. She ordinarily lays six eggs—one every day; but each egg is to be taken away as laid, leaving an ivory one only; and when she has done laying, replace all the six. The period of incubation is thirteen days. When the young are hatched, finely minced egg and bread should be placed near the feeding-trough, to enable the parents to carry suitable food to their young. Canaries will mate with siskins, linnets, several of the finches, and other allied birds, producing in many instances highly esteemed mules.

The system of treatment now described is also well adapted for the siskin, of which there are several varieties, as the black, white, and speckled.

The *sky-lark* requires a roomy cage, at least eighteen inches long, nine wide, and fifteen high: the bottom should have a drawer, in which enough of river-sand should be kept for this scratching-bird to be able to roll and dust itself conveniently. It is also a good plan to have in a corner a little square of fresh turf, which is as beneficial as it is agreeable. The top of the cage must be of linen, since, from its tendency to rise for flight, it would run the risk of wounding its head against a covering of wood or iron-wire, especially before it is well tamed. The vessels for food and drink must be outside, or, which I prefer, a drawer for the food may be introduced in the side of the cage: sticks are not necessary, as the lark does not perch.

The *starling*, if well treated, soon becomes exceedingly familiar, and may be taught to whistle various airs, and pronounce words and short sentences with accuracy. For these ends, no cutting or slitting of the tongue is requisite—an operation as stupid and unnecessary as it is cruel and barbarous.

Parrots.—Under this head may be classed a number of beaked birds of similar character, as parrots, perroquets, cockatoos, and macaws, all possessing beautiful plumage of green, crimson, yellow, or grayish tints. They are chiefly from South America, and require the warmth of a dwelling-house to keep them alive in this country. All possess harsh voices, and would on that account be considered a positive nuisance by most persons, except for the oddity of their being able to repeat certain words; but this is a quality possessed by some in greater perfection than others. All the species of these birds may be treated much in the same manner. They are allowed a large cage, formed of strong wires, with thick round bars to perch upon, and a ring at top to swing from by their hooked beak. All the parts must be of tin, for they would soon peck wood to pieces. In Zoological Gardens, they are usually seen perched on a cross-bar of tin at the top of a staff, but chained by the leg to prevent their escape; but this method is not so favourable for their climbing, swinging, and grotesque manœuvres as a large roomy cage.

The food offered to parrots, macaws, &c., is chiefly bread steeped in milk, nuts, or any other simple article. Care must be taken never to give them anything containing salt or pepper.

The cockatoo is generally esteemed as of milder temper than the parrot. For ornamental pets, perroquets—many of which are not much larger than the common house-sparrow—are now very generally preferred; and though not quite so showy in plumage as the macaws, lories, and cockatoos, yet their tints are often extremely beautiful, and they never become offensive by screaming, which is too often the case with their larger congeners.

THE HONEY-BEE.

THE subject of Bees, which is equally extensive and interesting, has for many ages attracted the attention of mankind. The Sacred Writings, the most ancient of which we have any knowledge, shew in numerous places how strongly the fathers of the Jewish people had been impressed by the peculiarities in the natural history of the Bee; and we know that Aristotle and other philosophers of old Greece deemed the subject worthy of years of patient investigation. Virgil also, and many other Roman authors, dwelt on it with enthusiasm in their writings; while, in much later times, Swammerdam and other distinguished cultivators of science have pursued the same track with undiminished ardour. The most zealous of these inquirers was Francis Huber (born at Geneva 1750, died 1831), who, though labouring under the deprivation of sight, by the aid of his wife formed a most valuable collection of observations on the habits of bees, and to whose work—as yet the best of its kind—we shall have frequent occasion to refer. Societies have also been formed for the sole purpose of investigating this portion of natural history. A mere summary of the interesting essays, therefore, which this insect, so universally appreciated, has called forth, would occupy a very large space. On the present occasion, an attempt can only be made to cull from the most approved sources such details as may form a complete history of the Honey-bee, though at the same time it must necessarily be a concise one, along with directions for the practical management of this most useful insect.

Bees are arranged by zoologists into the family of the *Apidæ* (*apis*, a bee), in the order *Hymenoptera* (having four unequal membranaceous wings) of the Insect class. The Social Bees form the principal division of the family, their type being the *Apis mellifica*, the Honey-making, or, in common phrase, the Honey-bee. It is so called, not from an exclusive peculiarity, but because it is the species which has long yielded to man the rich product indicated in its name. As the observations to follow will have reference to the Honey-bee, it may simply be mentioned that the description of this species involves the leading features in the natural history of its less important congeners, the Wild or Humble Bees. (See ZOOLOGY.)

ANATOMY AND PHYSIOLOGY.

Of the family of the Social Bees, two species seem to exist in Europe, the one found in the north, and the other in the south; but, making allowance for a slight deepening of tint from brown to red in the rings of the body in the case of the more southerly insect, the description of the common hive-bee of Britain will apply to the other in all important respects. A hive of honey or garden bees contains three ranks or sexes of inhabitants, the external characters of which differ considerably, while their uses and functions in the community are most obviously distinct. The most important, and by far the most numerous rank, is that of the *workers*, or working-bees, formerly regarded as neuters in respect of sex, but now more properly considered as undeveloped females. The second rank is composed of the males of the hive, termed the *drones*. There is usually but one perfect member of the third rank present at a time in a hive, and this is the *queen*, or mother-bee, the sole female of the community.

Workers.

The working honey-bee has a body about half an inch in length, blackish-brown in hue, and covered with close-set hairs, which are feather-shaped, and assist the creature materially in collecting the farina of flowers. The *head*, which is a flattened triangle in shape, is attached to the chest by a thin ligament; and the chest or *thorax*, which is of a spherical form, is united in a similar way to the *abdomen* (see No. 9). The abdomen is divided into six scaly rings, which shorten the body by slipping over one another to a certain extent. These three external divisions of the insect's body have all of them appendages of peculiar interest and utility. The head is provided with a double visual apparatus. In front are placed two *eyes*, consisting each of numerous hexagonal plates, studded with hairs, to ward off the dust or pollen of flowers; and three small eyes are also to be found on the very top of the head, intended, doubtless, both to heighten the general sense of seeing, which the creature so peculiarly requires, and to give a defensive vision upwards from the cups of flowers. The *antennæ*, however, which are two slender horns springing from betwixt the front eyes, and curving outwards from each side, most probably fulfil many of the purposes of vision in the dark interior of the hive. These instruments have each of them twelve articulations, and terminate in a knob, gifted with the most delicate sensitiveness. By the flexibility of the antennæ, the bee is enabled to feel and grasp any object in its way; and there can be little doubt that it is chiefly by means of these it builds its combs, feeds the young, fills the honey-cells, and performs the other operations of the hive. Bees also use these appendages for the recognition of one another.

The mouth of the bee is a very complex structure, and one wonderfully fitted for its duties. Its most important parts are the *mandibles*, the *tongue*, the *proboscis*, and *labial feelers*. The mandibles are merely the two sides of the upper jaw, split vertically, and movable to such a degree as to enable the insect to break down food betwixt them, to manipulate wax, and use them otherwise as serviceable tools. They are furnished with teeth at their ends, two in number. The tongue of the bee is extremely small, and indeed is scarcely admitted by some naturalists to exist at all, the proboscis being often signified by that name. Many of the usual functions of such an instrument are indeed performed by the proboscis, a long slender projection, composed of about forty cartilaginous rings, fringed with fine hairs. From the base of this, on each side, rise the labial feelers, instruments also fringed or feathered interiorly; and outside of these are the lower jaws, similarly provided with hairs. When the feelers and jaws close in on the proboscis, they form a sheath or defence to it. Naturalists used to term the proboscis a tube; but they now know that it acts by rolling about and lapping up, by means of the fringes around it, everything to which it is applied. The gathered material is then conveyed into the gullet at its base, whence it passes into the internal organs. Thus we find the mandibles of the upper jaw ready to break and prepare the food for the sweeping-up apparatus of the lower parts. While perfect in action in an expanded state, the whole, moreover, can be so folded or coiled together, as to form one strong well-protected instrument.

To the trunk or thorax of the bee exteriorly are attached the muscles of the wings and legs. The wings consist of two pair of unequal size, which are hooked to one another, in order to act in concord and steady the movements in flying. The bee has three pair of legs, of which the anterior pair are the shortest, and the posterior the longest. All of them are formed upon

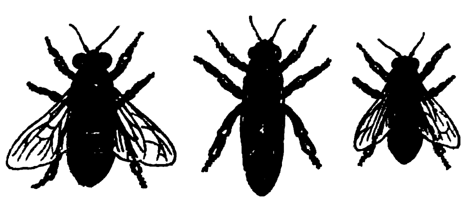
the same principle as the limbs of man, having articulations for the thigh, leg, and foot, with some minor joints in the latter part. The hind-legs are marked by a special and beautiful provision: this is a cup-like cavity on the *tibia* or fore-leg, intended for the important purpose of receiving the kneaded pollen which the bee collects in its wanderings. The legs are all thickly studded with hairs, and more particularly the cavity mentioned, in which the materials require to be retained securely. Another provision of the bee's limbs consists in a pair of hooks attached to each foot, by means of which the animal suspends itself from the roof of the hive or any similar position. Beneath or behind the wings, the *spiracles* or air-openings are found, which admit air for the purpose of permeating the chest and probably the whole body, for the oxygenation of the circulating system. Huber completely proved both that respiration is essentially necessary to bees, and that the spiracles are the instruments by which it is effected. He found that they die in an exhausted receiver, and become asphyxiated when shut up in numbers in close bottles. They perish in water only if the spiracles are under the surface; and the use of these apertures is then made apparent by the bubbles which escape from them under water. As will be shewn, also, bees carefully ventilate their hives. Therefore, though no blood has been detected in bees or other insects, these tiny spiracles are of no slight consequence in the physical economy of the insect, oxygen being apparently not less necessary to the vitality of its circulating fluids than to those of warm-blooded animals.

Besides these appendages and contents of the chest, that region is traversed by the *œsophagus* or gullet, on its way to the digestive and other organs situated in the abdomen. These organs consist of the *honey-bag*, the *stomach*, the *wax-pockets*, and the *intestines*, with the *venom-bag* and *sting*. The honey-bag, sometimes called the first stomach, though digestion never takes place there, is an enlargement of the gullet into a pea-sized bag, pointed in front, with two pouches behind. In this receptacle is lodged the fluid or saccharine portion of the bee's gatherings, and by the muscularity of the coats, it can be regurgitated to fill the honey-cells of the hive. A short passage leads to the second or true stomach, which receives the food for the nourishment of the bee, and also the saccharine matter from which the wax is secreted. The small intestines receive the digested food from the stomach, and from them it appears to be absorbed for the purposes of nutrition. Wax, it was once thought, was pollen elaborated in the stomach and ejected by the mouth; but it is entirely derived, it is now known, from the honey or saccharine matter consumed by the insect; and John Hunter discovered two small pouches in the lower part of the abdomen, from vessels on the surface of which it is secreted. After accumulating for a time in these pouches, scales of it appear externally below one or other of the four medial rings of the abdomen, and are withdrawn by the bee itself or those around it. Close to the stomach is found the last important organ of the abdomen, the sting. Much beautiful mechanism is observed on a microscopic examination of this weapon, so powerful in comparison to its bulk. It consists of two long darts, adhering longitudinally, and strongly protected by one principal sheath. This sheath is supposed to be first thrust out in stinging; and its power to pierce may be conjectured from the fact that, when viewed through a glass which magnifies a fine needle-point to the breadth of a quarter of an inch, the extremity of the sheath ends so finely as to be invisible. The sheath once inserted, then the two still finer darts follow, and make a further puncture. The use of this is to receive the poison, which is conducted to the end of the sheath in a groove; and in order that the conjoined darts may not be withdrawn too soon for this purpose, they have each nine or ten barbs at the point to retain them. When the weapon is withdrawn, the poison is thus left with a cavity to enter, causing a deeper festering. The insect ejects the poison by means of a muscle encircling the bag at the base of the sting, in which bag the venom is secreted. The chemical composition of the poison has not been discovered, though it has so far the nature of an acid as to redden the vegetable blues. Altogether, Paley, in his *Natural Theology*, is fully justified in pointing to the defensive weapon of the bee as a wondrous union of mechanical and chemical perfection.

The manner in which the bee collects the food which forms the various secretions alluded to, is worthy of note. The hairs with which its body and feet are covered, are the main instruments used for this end. By means of the hairs on the feet, the insect usually begins its collection of the pollen in the corolla which it has entered, and after kneading the dust into balls, finally places it in the baskets of the hind-legs. But the creature is not content with the product of this process. Rolling its body round and round, it brushes off the pollen still more cleanly, gathers it into two heaps with its active brushes, and loads its baskets to the brim. Even afterwards, they sometimes fly home like dusty millers, and brush their jackets when unloaded. The pollen is understood to be brought home by the working-bees more peculiarly as food for the young. The fluid secretions contained in the nectaries of flowers, and honey-dew, which is a deposition of certain aphides on plants, serve as other natural varieties of the bee's food. The insect is also at certain periods a liberal drinker of water.

The senses of bees have been in part touched upon already. The means of *vision* bestowed on them, it was mentioned, consist of the many-lensed eyes in front, and the supplementary organ above. Inquirers have been staggered by the seeming contradictions connected with the vision of the bee. After collecting its store of food, its first movement is to rise aloft in the air, and look for the site of its home. Having determined this in an instant, however distant the hive may be, it goes for the point with the directness of a cannon-ball, and usually alights at its own door, though the whole country be crowded with hives. Yet if the hive, or its door, has been shifted to a slight extent, the insect seems confused, and cannot find its way. The conclusion from this is, that the eyes of the bee have a lengthened focus, suiting them for the main purposes of its existence. But the consequent inability to determine accurately on short distances has been compensated to the creature by the antennæ, which then become a highly serviceable resource. The sense of *taste* in bees has been the subject of much argumentation. Huber was of opinion that it was the most imperfect of their senses, and they have been observed to resort to putrid marshes for water, even when they were not restricted in their choice. Xenophon found his men seriously injured by taking honey produced by bees which had fed on deleterious plants. But, on the other hand, it has been noticed that they reject many substances, and prefer others, when a choice is allowed them; and it has been conjectured that they go to marshes purposely for the salt in their waters. Moreover, what renders the honey deleterious to man, may not be hurtful to bees. Honey formed from a particular flower in the Jerseys, was found unfit for use from its intoxicating qualities; yet the bees throve wonderfully upon it all the while. Their taste in selecting the richest flowers is likewise unquestionable. No doubt the sense of *smell* comes into operation on these occasions, as well as the sense of taste. Betwixt the influence and effects of the two, indeed, it is scarcely possible to discriminate. Even in the case of the human being, it is an established fact, that the powers commonly ascribed to the sense of taste are to a remarkable degree dependent on the sense of smell. If the eyes be bandaged, and the apertures of the nose well shut up, the most experienced

judge will be at a loss to determine between any two kinds of ardent spirits, or other pungent substances. The most nauseous medicines, also, much as they may usually seem to affect the taste, will be found almost insipid if the site of the sense of smell be closed up while they are swallowed. In bees, the site of the two senses seems to be almost one and the same. Many experiments of Huber seem to prove that the sense of smell lies in the mouth, and that it is very acute. He found that they hate the odour of turpentine; yet on plugging up the mouth, they shewed no disgust when placed beside that liquid. He concealed honey at considerable distances, and they in a very short time detected the hidden treasure. The acuteness of their sense of smell, in truth, is sufficiently proved by their admirable skill in tracking out, over hill and dale, the most fragrant flower-parterres and beds of mountain-heath. The sense of *hearing* has been denied to bees by many observers, while others describe the antennæ as their organs of hearing. The probabilities are in favour of the latter position. Noise, produced by the wings, and varied to suit particular purposes, is well known to be used as a mean of intercommunication; and Huber, though doubtful about the faculty, avers that by a particular sound, emitted from the mouth apparently, the queen will render the whole hive silent and motionless in one instant. A certain sound, too, heard in the hive before swarming, is always followed by definite consequences. Such facts as these go far to establish the possession of hearing by bees; as signals by sound, made when the eyes could not detect the movement attending their production, would otherwise be valueless. The antennæ have been mentioned as possessed, if not of hearing, at least of a delicate sense of *touch*. Huber points out a moonlight night as the best time for observing the uses of the antennæ in this respect. The bees, guarding against the intrusion of moths, have not light enough to see fully, and they circumambulate their door with the antennæ stretched right before them. The instant a moth is felt, it is destroyed. When the queen of a hive is lost, the antennæ form a curious means of spreading intelligence. Bee after bee protrudes its antennæ, and crossing them with those of his next neighbour, disseminates in this way the sad news over the hive. Besides the antennæ, the feelers have been shewn by experiment to possess a considerable degree of sensibility, and to serve in part as organs of touch.



Drone. Queen. Worker.

Such are the anatomical and physiological characteristics of the common or working bee. The duties of this order include almost the whole business of the bee community, as will be shewn afterwards in detail. Hives differ greatly, of course, in the number of their inmates, taking them even at the same season. Some contain but a few thousands; others from twenty to thirty, forty, and even fifty thousand. Of these the drones compose but a thirtieth part, or little more; all the rest, with the exception of the queen, are workers.

Drones or Males.

The drones differ considerably in outward appearance from the workers: they are bulkier and flatter in body, with a round head, a shorter proboscis, and antennæ with an additional articulation; they have no basket-cavity on their hind-legs, and their abdomen contains the means of secreting neither honey, wax, nor poison, while the reproductive organs are there found instead. They are called drones from the peculiarly loud noise which they make with their wings. It has been already stated that the drones are the males of the hive. They live but for the reproduction of the race, and when the object of their existence is accomplished, they are doomed to die. The workers, who have their own winter food and that of the coming young to provide, instinctively pass sentence of death at the fitting time; despatch the defenceless males with their stings, and cast them forth from the hives, in which, from their size and voracity, their presence has now become a positive evil. With these exceptions, the description given of the worker-bee applies also to the drone.

Queen-bees.

The queen-bee is of larger size than either the drone or the worker: she has an elongated body, blackish above, and tinted with yellow inferiorly, while the presence of two ovaries or egg-receptacles in the abdomen demonstrates her sex. She has also a sting, considerably bent. The Germans call the queen the *mother-bee;* and this is the most appropriate name, since her functions are those of a parent rather than a potentate. Her sole province is to lay the eggs, from which issue those annual multitudes that perpetuate the race in new communities. The progress of all kinds of bees, from the larva state to maturity, will fall to be described in an ensuing section; but it may in the meantime be observed, that the queen usually commences laying eggs on the fifth day after she has assumed the perfect state, and often continues without intermission from early spring to the end of September, laying in the warmest season about two hundred eggs a day. Such are the distinguishing characteristics and functions of the mother-bee.

We propose now to give an account of the natural and regular operations of a colony of bees, from the moment of their introduction to an unfurnished habitation, to the establishment of a perfect hive.

NATURAL ECONOMY OF THE HIVE.

The breeding of young bees commences in February, and a hive, however thinned by the previous winter, becomes, under ordinarily favourable circumstances, crowded to excess in midsummer. Besides the developed bees, it abounds in eggs and young ones not matured. That fine instinct which, in the case of bees, occasionally prompts to acts almost above the power of reason, relieves this crowded state of things. The queen-bee, the proper mother of at least the great body of the hive, resolves upon departure with a swarm. The phenomena attending that departure will be noticed under a separate section; in the meantime, let it be supposed that the queen has led off a colony, and that, by the care of the owner of the bees, the swarm is lodged in a new and empty hive.

The first object of the community is to clean out their new lodging thoroughly, if they find this not done beforehand. The next great object is to block up all the chinks of the hive, smooth its projecting parts, and lay a stable foundation for the future works of the interior. Besides the wax which they use so extensively in their architecture, bees also employ, particularly at first, a remarkable substance called *propolis*, from the Greek words *pro* and *polis* (before the city), as indicating its use on the superficial parts of the hive. Propolis is a grayish-brown resin, of an aromatic odour, and better fitted by its tenacity for cementing than wax. Huber first shewed distinctly that the bees gather this from the poplar, alder, birch, and willow trees, but more especially from the first of these trees. That ingenious naturalist, suspecting Reaumur to be wrong in referring the propolis to the pine, placed near his hives some wild poplar branches, which the bees soon discovered, and flocked to in great

numbers. In the heat of the day, when the viscous matter is ductile, it is thus carried off by the insect. A small thready portion is detached, kneaded with the mandibles, and then, by means of the fore-feet, placed in the basket of the hind-legs, a smart pat or two being given to secure it there. Another portion, similarly kneaded to make it portable, and a little drier, is basketed in the same way, till as much is procured as the insect can carry. Sometimes the patient creature will spend half an hour in the mere kneading of a portion of propolis; and occasionally other bees will come behind and rob the little labourer of its whole load, for a succession of times, without eliciting the slightest symptom of impatience. When a bee reaches the hive with its load, the propolis adheres so firmly, that the insect has to present its limbs to the workers in the hive, who detach it, and immediately use it, while yet ductile, to fill all the crevices of the hive, and smooth the projecting parts, so as to prevent hurts being received in the dark. Another remarkable use is made of the propolis. From the hour of their entrance into the hive, bees are liable to the intrusion of other creatures. A fly they can soon remove, but what are they to do with a snail? They can sting it to death, to be sure, in an instant, but their puny strength is totally insufficient to remove the carcass. In this dilemma, they completely obviate the disagreeable effects of the presence of a large putrefying body, by covering it with propolis, which hardens over the mass, and gives a pleasant aroma in place of a fetid odour. With the propolis, moreover, they often narrow the entrance to the hive, forming a secure barrier, when they have reason to dread the intrusion of the death's-head moth, their great enemy in some countries.

In the meantime, while some workers are using the propolis for the purposes first stated, others are commencing the preparation of the cells or combs. The propolis is employed to attach these to the edges of the hive, but wax is the component material of the cells themselves. We shall find, in noticing the after-arrangements of the completed hive, that the working-bees are naturally divided into two great classes; but at the outset of their labours, when the cells are being constructed, they form *three* sections, each of which pursues its allotted toil with admirable order and regularity. One section produces the material for the combs, and forms it roughly into cells; the second division follows the first, examines and adjusts the angles, removes all the superfluous wax, and perfects the work; while the third band passes continually out and in, seeking and bringing provisions, chiefly pollen, for the second section, which never quits the hive. The first class fly abroad at intervals, it being necessary that they should have rich saccharine food for the secretion of the wax. As the secretion goes on best in a state of repose, bands of the wax-producers, after feeding fully, suspend themselves in clusters from the roof, each hanging from the hind-legs of the one above, till the wax-scales are formed, and they are prepared to take up the work. This clustering occurs on the very entrance of a swarm into a hive, when a seeming inactivity of several hours takes place, till the production of wax is set agoing. It will be seen that the second section, the architects proper, have the most unremitting toil to perform. They never quit it when once begun, excepting to turn to the little waiters of the third section, and indicate their hunger by holding out their trunk, when the caterer either spirts out a drop or two of honey, or furnishes pollen from the stores brought in.

Cells.

But if the labour of the architect class be severe, their work, when complete, is a marvel of instinctive ingenuity. Bees always begin their work, in ordinary circumstances, at the ceiling, suspending their structures from it. Their combs, or clusters of cells, are arranged in vertical and parallel plates, with a space of about half an inch betwixt contiguous pairs; and each comb is nearly an inch in thickness. At the outset, when one wax-making bee leaves the suspended cluster alluded to, and lays the foundation of a cell, others follow in rapid succession, not only adding their wax to that of the first, but soon commencing new combs, one on each side; and so the work goes on, in most cases, until the whole roof is covered with foundations. The architects proper, also, are meanwhile at their finishing-work. They have, says Reaumur, to solve this difficult geometrical problem: 'A quantity of wax being given, to form of it similar and equal cells of a determinate capacity, but of the largest size in proportion to the matter employed, and disposed in such a manner as to occupy the least possible space in the hive.' Wonderful to reflect upon, this problem is solved by bees in all its conditions, in their construction of hexagonal or *six-sided* cells. The square and the equilateral triangle are the only other two figures which could make the cells all equal and similar without interstices. But cells of these figures would have either consumed more material or have been weaker; and they would also have occupied more space, being less adapted to the form of the bee. In short, the hexagonal form combines all the requisites of economy and capacity. Another wonderful arrangement is seen in the construction of the bottoms of the cells. Each of these is composed of three rhombs, or plates of wax in the shape of card-diamonds, disposed in such a manner as to form a hollow pyramid, the apex of which forms the angles of the bases of three cells on the opposite side, giving to each of them one of the three diamond-shaped plates which is required to form their bases. Now, the three rhombs, composing each cell-bottom, have the two obtuse angles each of 110 degrees, and, consequently, each of the two acute angles of 70 degrees. Koenig, on being desired by Reaumur to calculate the exact angle which would give the greatest economy of wax in a cell of such capacity, found that the angle should be 109 degrees 26 minutes, or 110 degrees nearly. Other geometricians have arrived at similar conclusions. The problem is one of great difficulty, yet the bee practically solves it at once, under the guidance of the Great Geometrician who made both the bee and the law on which it proceeds. Attempts have been made to ascribe the form of the cells to the peculiar shape of the head of the bee, and the instruments which it employs; but all such explanations have been found liable to insuperable objections.

The cells of the bee are extremely delicate, two or three plates or sides being of the consistence only of a common leaf of paper. They are made strong, however, by mutual support and other means. Besides a sort of froth which the insect mixes with the wax, the cells, at first of a dull white, soon appear yellow on the interior, the change arising from the plastering over them of a compound varnish of wax and propolis. Each cell is soldered, too, at its mouth by a similar compound of a reddish colour, having in it more propolis; and threads of the same substance are laid around the walls, to bind and strengthen them. It is now to be observed that all cells are not alike. They have four different uses in the economy of the hive, and are constructed variously to suit these. One set of cells is for holding the eggs or embryos of worker-bees; a second for those of males or drones; a third for those of young queens, hence called royal cells; and a fourth set are for the reception of honey and pollen. The first are generally about five lines in depth (or less than half an inch), and two lines and two-fifths in diameter. The cells of the young males are much less numerous, and measure from six to seven lines in depth, by three and a half in diameter. It is worthy of note, that in passing from the construction of worker-cells to those of drones, in the same comb, the architects do not alter the size at once, but gradually, thus disordering in the slightest possible degree the delicate arrangement of the bases of the cells. In shifting from larger to smaller, the same rule is observed. A small

number only of royal cells, about ten or twelve, are constructed on ordinary occasions. They are about an inch in depth, and nearly one-third of an inch in width, with walls about an eighth of an inch in thickness. After the breeding season is over, the cells both of worker and male bees are used for holding honey. Those made purposely for that end are chiefly marked by a greater divergence from the horizontal plane, that the honey may be better secured; and it is curious to observe that, in a very warm season, these wise insects give the floor a still greater dip from the mouth inwards. As the store enlarges, they seal up the mouth with a ring of wax, to which they gradually add concentric layers till the cell is filled, when they close it altogether—reserving its treasure for use during winter and spring. Pollen, as brood food, is kept in cells of considerable size.

Laying of Eggs.

A very short time elapses ere a great number of cells are constructed; for, in the height of the honey season, a good swarm has been known to build *four thousand* in a day. The queen-mother very soon begins the task of laying eggs. A thousand conjectures have been hazarded as to the mode in which the fecundation of the female bee takes place. No observer has yet been able to discover any contact with the drones in the hive. It was supposed by Swammerdam that a certain aura or odour from the males was all that was necessary to render the eggs of the queen productive; while M. Debrau imagined that the eggs, as in the case of frogs and fishes, were fecundated by a fluid from the drone after being laid. M. Hattorf thought, again, that the queen was fecundated by herself alone. All these opinions Huber refuted in a satisfactory manner, by separations and confinements of the insects in various ways. He at length came to the belief, founded on experiments which appear almost decisive of the question, that the female bee never becomes fruitful in the hive, but requires to go abroad for that purpose; and it has been also thought probable that the fecundation takes place by contact in the air, as is known to occur in the case of winged ants. The number of drones in a hive has been thought a most unintelligible circumstance. Huber's views explain the matter fully. It is essential that they should be numerous, that the female may have a chance of meeting them abroad; and it is to be observed that she always quits the hive at the hour when the drones leave it, or immediately afterwards. One intercourse is sufficient, according to Huber's experiments, to render the female bee productive for at least two seasons; and if the intercourse takes place at the end of the year, the consequent laying of eggs may be deferred till the ensuing spring. The cold weather has a powerful influence in this respect.

M. Huber discovered that the queen begins to lay eggs forty-six hours after returning from the flight during which fecundation takes place. For the space of eleven months, under ordinary circumstances, a queen, at her first laying, produces the eggs of worker-bees alone. At the end of the space mentioned, a considerable laying of the eggs of drones commences; and soon after the appearance of these, the workers of the hive, with a strange instinct, begin to prepare royal cells for the queen-eggs that are certain to follow. Altogether, the fruitfulness of the female bee is amazing, from 100 to 200 eggs a day being the usual amount of her produce: 100,000 is said to be no very uncommon number of young for her to give origin to in a single season. A swarm consisting of 2000 or 3000 in the beginning of the year, will throw off in June swarms amounting to 40,000 or 50,000; in many cases the first swarm, and in some the cast or second swarm, throw off colonies of 10,000 or 12,000; and yet the original stock is left augmented to the number of 18,000 or 20,000. Occasionally, an early and numerous first swarm casts even twice.

Transformation of Worker-bees.

A fertilised queen is so impatient to begin her laying of worker-eggs, that in a new hive, she only waits till a few inches of comb are erected. Before depositing the egg, she carefully examines the cell, and, if satisfied, turns and drops into it from the oviduct, an egg of an oval shape and bluish-white tint. Here the egg remains for three days attached by a viscous fluid to the corner of the cell; and, on the fourth, the thin outer shell of the egg bursts, exposing a small lively worm. Now come into play the *nurses* or nursing-bees, one of the two great sections into which Huber and others consider the labours of the hive to be divided. The other class are the *wax-workers*. Both elaborate honey, but the latter class alone make wax and form combs. Again, the nurses, whose figure may be distinguished from its being more ovoidal than the others, are those who alone take care of the young. As soon as the egg is hatched, they watch over the larva or worm with the tenderest and most incessant care, administering copious supplies of mixed pollen, honey, and water, which the nursling devours with avidity. Like other larvæ, it soon grows so as to cast its cuticle; and, five days after chipping the shell, it has become large enough to fill the cell, lying coiled up like a ring. It now ceases to eat, and the bees seal up the cell with wax. Left to itself, the larva begins the process of spinning a cocoon round its body, which it does in thirty-six hours, the material being a fine silken thread from the mouth of the spinner. In three days more it is converted into the state of *pupa* or chrysalis, when all the parts of the future bee become gradually visible through the transparent covering, assuming a darker hue day by day, and progressing to the state of the complete *imago* or insect. On the twentieth day from the deposition of the egg, the young bee begins to cut through its prison-door with its mandibles, and in half an hour makes its escape. Old writers say that the elder bees fondly caress and feed the new-comer; but later observers, of no mean authority, declare that, on the contrary, they seem to think their duty ended with the closing up of the cell, and leave the young stranger to shift for itself in the busy world upon which it has entered. One thing, however, is done by the elder bees: they instantly clean out the vacated cell, and prepare it again for eggs or honey, leaving at the same time the silk cocoon adhering to the walls.

Male Eggs—Royal Eggs.

The passage of male eggs through the larva and pupa state is attended with the very same phenomena as in the case of the eggs of workers, with the exception that the process occupies a little more time, twenty-four days in all being spent in the change. The cause of male eggs being laid, in ordinary circumstances, only after eleven months have been passed in the laying of worker-eggs, was explained by Huber. He conceived eleven months to be necessary to perfect the male eggs, and was of opinion that the arrangement of the eggs in the ovaries was such as to permit, and even compel, the retention of both male and royal eggs until they were fully matured. This idea seems to be confirmed by the ordinary course of things in the hive, but certain anomalous facts startlingly contravene it. Huber himself found, that if a young queen had not the opportunity of proving fertile within twenty days of her birth, all her after product consisted of drones, and drones alone; and, what is still more curious, he discovered that she began to produce these drones at the time when she should have laid worker-eggs—namely, within forty-six hours after fecundation. The gestation of eleven months seemed totally unnecessary in such cases of retarded fecundation. Huber confessed himself incapable of explaining this remarkable circumstance. Though we do not understand it, however, it only tends to make us marvel more and more at the perfection of order in the

bee economy. The queen-bee is never voluntarily guilty of that breach of the laws of her being, which produces such remarkable effects; and, if artificially confined till she is twenty days old, her violent agitation shews her instinctive sense of the departure from the order of nature.

The raising of workers and drones from the egg to the insect state is a simple matter in comparison with the same transition in the case of queen-bees. The royal eggs, which the queen begins to lay twenty days after she has commenced the deposition of male ones, differ in no respect from common eggs. But on the royal larva, when it breaks from its three days' confinement in the shell, the nurses bestow peculiar attentions. They watch it incessantly, and feed it with a rich *jelly*, slightly acidulous, and given in such quantities that the royal cell is usually wet with it. In five days the young majesty of the hive has grown, so as to be able to spin her web, and the bees wax up the cell. The cocoon is spun in twenty-four hours; two days and a half of inactivity follow; the larva is then transformed into a pupa, or a *nymph*, as the insect in this state is more frequently termed; and after other four or five days have passed, the royal insect is complete—the whole time occupied in the metamorphosis being about sixteen days.

Young Queens.

We have now arrived at one of the most extraordinary points in the history of the hive. The young queen, or rather queens, do not issue from their cells when perfect, like workers and drones. They are not permitted, unless the old or regnant queen has quitted the hive with a swarm, or the seat of royalty is in any other way vacated. The bees therefore close the royal cells more firmly, leaving only a small aperture to introduce food; and, acting as if aware that they may need a queen in case of swarming, they at such times will not permit the old queen to approach the cells. Her struggles to do so are often violent, and her dire hostility to her own sex leads her, if she gets near the cells, to destroy them instantly, whether in the state of full insect or nymph. The strength of this instinctive hate is even such, that a young queen no sooner leaves her own cell than she feels its stirrings.

According to Huber, there can only be a single queen in a hive. The first thought of a young queen, it has been seen, is to kill her yet undeveloped rivals. Nature has given her the chance, for, as more queen-eggs than one are seldom laid daily, one is usually the oldest. If, however, two do quit the cell at the same instant, they rush into combat with the most headlong fury. If a stranger enters a hive, its queen-regnant flies to the field without a moment's hesitation. In short, in all ordinary circumstances, two queens brought into contact, fight. But they might *both* die in the contest, and the community be left without a queen. Nature demands but one victim, and she has arranged that but one victim shall fall. Bees are only vulnerable in the belly; and Huber observed that, whenever two royal combatants were so locked together that they could mutually plant their stings in the fatal part, their instinct caused them to separate precipitately, without harm on either side. The combat only closes when one can get an advantage of position, and kill its rival with safety. Again, the worker-bees might interpose to prevent these mortal combats. On the contrary, their instinct is to prevent the queens from parting, and force on a fatal issue. Alluding to one battle, Huber says that it seemed as if 'the bees anticipated the combat in which these queens were about to engage, and were impatient to behold the issue of it, for they retained their prisoners only when they appeared to withdraw from each other; and if one less restrained seemed desirous of approaching her rival, all the bees forming the clusters gave way, to allow her full liberty for the attack; then if the queens testified a disposition to fly, they returned to enclose them.'

Another remarkable provision for insuring the existence of but one queen in a hive, is beheld in the peculiar mode in which the royal larvæ spin their cocoons. Other bees spin perfectly close cases; the queen-larvæ spin cocoons which envelop only the head, thorax, and first ring of the abdomen, leaving a part open behind. Huber thus explains this minute but important peculiarity:—'Of several royal nymphs in a hive, the first transformed attacks the rest and stings them to death. But were these nymphs enveloped in a complete cocoon, she could not accomplish it. Why? Because the silk is of so close a texture, that the sting could not penetrate, or if it did, the barbs would be retained by the meshes of the cocoon, and the queen, unable to retract it, would become the victim of her own fury. Thus, that the queen might destroy her rivals, it was necessary the last rings of the body should remain uncovered; therefore, the royal nymphs must only form imperfect cocoons. Hitherto philosophers have claimed our admiration of nature in her care of preserving and multiplying the species. But from the facts I relate, we must now admire her precautions in exposing certain individuals to a mortal hazard.'

Loss of a Queen.

If bees, by death or artificial means, are deprived of their queen, the event has a marked influence in the hive. In such a case, the following results ensue, according to Huber:—'Bees do not immediately observe the removal of their queen; their labours are uninterrupted; they watch over the young, and perform all their ordinary occupations. But in a few hours agitation ensues; all appears a scene of tumult in the hive. A singular humming is heard; the bees desert their young, and rush over the surface of the combs with a delirious impetuosity. Then they discover their queen is no longer among them. But how do they become sensible of it? How do the bees on the surface of the comb discover that the queen is not on the next comb?' It is supposed that the alarming intelligence of the loss is communicated by the strokes on the antennæ, which bees are uniformly observed to give to each other at these times. The insects then appear to seek for their lost queen, some rushing hurriedly out to make the search abroad. At the end of five hours, the commotion greatly ceases, and an instinctive recourse to the means of supplying the vacancy takes place. If they have royal larvæ, they turn their whole attention to them. If they have only the larvæ of working-bees, they immediately select two or three of them, pull down the neighbouring cells, at the cost of the lives of the young within them, and construct a royal cell around each of the selected larvæ—the consequence of which proceeding will be immediately explained. If they have no larvæ at all on the loss of their queen, still they build several royal cells, as if so far at least to supply the emergency. If a stranger queen be introduced in such a state of things, within twelve hours after the loss of their own sovereign, the new-comer is treated as an intruder, and the bees surround her so closely that she commonly dies from privation of air, suffocation being the resource of bees in such cases. If the stranger be introduced within eighteen hours, they also surround her, but leave her sooner. To shew that they possess memory, it is only necessary now to reintroduce their own queen, when they will shew every symptom of recognition and joy. But their memory is short-lived; for, if the stranger be not introduced till twenty-four hours elapse, she receives a treatment very different from that experienced at an earlier period. 'I introduced,' continues the ingenious naturalist, 'a fertile queen, eleven months old, into a glass hive. The bees were twenty-four hours deprived of their queen, and had already begun the construction of twelve royal cells. Immediately on placing this female stranger on the comb, the workers near her touched her with their

antennæ, and passing their trunks over every part of her body, they gave her honey. Then these gave place to others that treated her exactly in the same manner. All vibrated their wings at once, and ranged themselves in a circle around their sovereign. Hence resulted a kind of agitation, which gradually communicated to the workers situated on the same surface of the comb, and induced them to come and reconnoitre, in their turn, what was going on. They soon arrived; and having broke through the circle formed by the first, approached the queen, touched her with the antennæ, and gave her honey. After this little ceremony they retired, and, placing themselves behind the others, enlarged the circle. There they vibrated their wings, and buzzed without tumult or disorder, and as if experiencing some very agreeable sensation. The queen had not yet left the place where I had put her, but in a quarter of an hour she began to move. The bees, far from opposing her, opened the circle at that part to which she turned, followed her, and formed a guard around. She was oppressed with the necessity of laying, and dropped her eggs. Finally, after an abode of four hours, she began to deposit male eggs in the cells she met with.

'While these events passed on the surface of the comb where the queen stood, all was quiet on the other side. There the workers were apparently ignorant of a queen's arrival in the hive. They laboured with great activity at the royal cells, as if ignorant that they no longer stood in need of them: they watched over the royal worms, supplied them with jelly, and the like. But the queen having at length come to this side, she was received with the same respect that she had experienced from their companions on the other side of the comb. They encompassed her, gave her honey, and touched her with their antennæ; and, what proved more satisfactorily that they treated her as a mother, was their immediately desisting from work at the royal cells: they removed the worms, and devoured the food collected around them. From this moment the queen was recognised by all her people, and conducted herself in this new habitation as if it had been her native hive.'

Making of a Queen.

If one queen is not so introduced to supply the loss of another, and no royal larvæ exist, one of the most wonderful phenomena of the hive takes place. It has been stated that bees, on losing their queen, build a royal cell around an ordinary worker-bee larva, or several of them, if the larvæ are abundant. These, by peculiar feeding, are formed and developed into *queens*, thus proving that the worker-bees, commonly viewed at one time as neuters, are in reality undeveloped females. This remarkable discovery was made by Schirach. Having used smoke about a hive, he so annoyed the queen that she flew away, and the circumstance of the bees immediately building royal cells around common larvæ, when they had no royal larvæ, revealed to him the truth. Huber proved the same thing by the succeeding experiment:—'I put some pieces of comb, containing workers' eggs in the cells, of the same kind as those already hatched, into a hive deprived of the queen. The same day several cells were enlarged by the bees, and converted into royal cells, and the worms supplied with a thick bed of jelly. Five were then removed from these cells, and five common worms, which, forty-eight hours before, we had seen come from the egg, substituted for them. The bees did not seem aware of the change; they watched over the new worms the same as over those chosen by themselves; they continued enlarging the cells, and closed them at the usual time. When they had hatched on them seven days, we removed the cells, to see the queens that were to be produced. Two were excluded, almost at the same moment, of the largest size, and well formed in every respect. The term of the other cells having elapsed, and no queen appearing, we opened them. In one was a dead queen, but still a nymph; the other two were empty. The worms had spun their silk cocoons, but died before passing into their nymphine state, and presented only a dry skin. I can conceive nothing more conclusive than this experiment. It demonstrates that bees have the power of converting the worms of workers into queens, since they succeeded in procuring queens by operating on the worms which we ourselves had selected.' This curious provision seems intended to preserve the communities of bees, in any emergency, from the danger of wanting that all-important member, the queen; and it is reasonably conjectured that the evolution of a queen from a worker-larva is dependent on the effects of the royal food upon the ovarian system.

Fertile Worker-bees.

Another most remarkable fact observable in the economy of the hive was discovered by M. Riem. Common worker-bees, that naturalist proved, sometimes lay fertile eggs. It was reserved for Huber to determine this, and also to explain the cause. He in the first place found that, in a hive deprived of its queen, the eggs of drones were laid. Though he did not put faith in what had been said by some naturalists respecting the existence of *small* queens, he nevertheless satisfied himself, by directing a careful examination to be made of each individual bee in the hive, that no queen was amongst them, every one having the little basket on the hind-leg, and a straight sting. Thus convinced of the reality of Schirach's discovery, Huber, having detected several workers laying eggs, examined them, and found the ovaries partially developed. He now bethought him that the only known cause of such development is the use of the food or jelly given to the royal larvæ. Led into this train of thought, he speedily discovered that all the fruitful worker-bees are born in hives where no queen exists, and where worker-larvæ are transformed to queens; and he further found that they are always born in cells adjacent to those of these larva-queens. Continued investigations brought him to the belief, finally, 'that when bees give the *royal treatment* to certain worms, they either by accident or by a particular instinct, the principle of which is unknown to me, drop some particles of royal jelly into cells contiguous to those containing the worms destined for queens;' whence the expansion of the ovaries to a certain degree. That expansion is imperfect. As in the case of retarded fecundation in queens, the fruitful worker-bees produce nothing but drones. Ovaries, in a rudimental or undeveloped state, have been found by late observers in all working-bees.

Mutilations of Queens.

Before leaving the particular subject of queens, the remarkable effects of mutilations upon them may be mentioned. Huber cut off one antenna from a queen without any marked effects; but when he cut off both, the case was different. 'From this moment there was a great alteration in her conduct. She traversed the combs with extraordinary vivacity. Scarcely had the workers time to separate and recede before her: she dropped her eggs without taking care to deposit them in any cell. The hive not being very populous, part was without combs. Hither she seemed particularly earnest to repair, and long remained motionless. She appeared to avoid the bees; however, several workers followed her into this solitude, and treated her with the most evident respect. She seldom required honey from them; but when that occurred, she directed her trunk with an uncertain kind of feeling, sometimes on the head, and sometimes on the limbs of the workers, and if it did reach their mouths, it was by chance. At other times she returned upon the combs, then quitted them, to traverse the glass sides of the hive; and always dropped eggs during her various motions. Some-

times she appeared tormented with the desire of leaving her habitation. She rushed towards the opening, and entered the glass tube adapted there; but the external orifice being too small, after fruitless exertion, she returned. Notwithstanding these symptoms of delirium, the bees did not cease to render her the same attention as they ever pay to their queens; but this one received it with indifference. All that I describe appeared to me the consequence of amputating the antennæ.' Another similarly mutilated queen was placed beside her; they had both lost their natural combativeness. Finally, on being again left alone, the poor mutilated queen quitted the hive, unheeded, and abandoned to her fate. This evidence of the indispensable utility of the antennæ was gained, on the whole, in a manner for which even a Huber's ardour for science can scarcely form an excuse.

Massacre of the Drones.

Another of the great natural phenomena of the hive is the massacring of the drones. It was at one time asserted that the worker-bees did not use their stings against the stingless males, but merely pushed them out to die. This idea, however, resulted from the massacre being always committed at the bottom of the hive, whither the poor drones retire in clusters in July and August, as if aware of the doom impending over them. As usual, by one of his ingenious expedients, Huber discovered the truth. Six swarms were put on glass tables, beneath which the watchers placed themselves. 'This contrivance succeeded to admiration. On the 4th of July, we saw the workers actually massacre the males, in the whole six swarms, at the same hour, and with the same peculiarities. The glass table was covered with bees full of animation, which flew upon the drones as they came from the bottom of the hive; seized them by the antennæ, the limbs, and the wings, and after having dragged them about, or, so to speak, after quartering them, they killed them by repeated stings directed between the rings of the belly. The moment that this formidable weapon reached them, was the last of their existence; they stretched their wings and expired. At the same time, as if the workers did not consider them as dead, as they appeared to us, they still struck the sting so deep, that it could hardly be withdrawn; and these bees were obliged to turn round upon themselves, with a screw-like motion, before the stings could be disengaged.

'Next day, having resumed our former position, we witnessed new scenes of carnage. During three hours, the bees furiously destroyed the males. They had massacred all their own on the preceding evening, but now attacked those which, driven from the neighbouring hives, had taken refuge amongst them. We saw them also tear some remaining nymphs from the combs; they greedily sucked all the fluid from the abdomen, and then carried them away. The following days no drones remained in the hives.

'The males are never destroyed in hives deprived of queens; on the contrary, while a savage massacre prevails in other places, they there find an asylum. They are tolerated and fed, and many are seen even in the middle of January. They are also preserved in hives which, without a queen, properly so called, have some individuals of that species that lay the eggs of males, and in those whose half-fecundated queens, if I may use the expression, propagate only drones. Therefore the massacre takes place in none but hives where the queens are completely fertile, and it never begins until the season of swarming is past.'

Swarming.

Swarming usually takes place, in temperate climes, in May and June, though additional swarms, and swarms from swarms, are commonly later. In noticing the proceedings of a community from its first settlement, it was mentioned that the old queen led off the first swarm, and did so as if under alarm at the number of royal embryos, usually from twelve to twenty, which were in progress to maturity, and which the worker-bees would not allow her to approach. Other causes also operate, beyond doubt, in a certain degree. The increased heat of the hive from crowding, for example, in all likelihood influences the movement. Bees cannot do without freedom of respiration and fresh air, and it has surprised many observers to find the air usually pure, and below 80 degrees, in a hive ordinarily filled. The insects, however, have been discovered to manage this by active ventilation in their own way. A number of them are always to be seen near the inner, and sometimes the outer side of the opening of the hive, vibrating their wings with great rapidity, and sending the entering air backwards in a smart current. One band relieves another at this task. These means of ventilation, however, seem to become comparatively ineffective when the hive gets overcrowded. The heat often rises to about 100 degrees; the bees are driven to the door in clusters, while the warmth makes the hive visibly moist. At the same time, the old queen's alarm at the growth of the royal young seems to have its influence. She would fain kill them, but the worker-bees lose all respect for her, biting and beating her off with violence. The way in which they defend the royal young at swarming time, is indeed most remarkable. If, at any other season, they bring up queens from worker-larvæ, the first queen that leaves the cell is allowed to kill the rest at pleasure. But when casting colonies, the workers, as if from the sense that various swarms may be cast off, and various queens required, will not permit the old queen to touch the young, whom nature has given them the strange power of keeping alive, for better security, in their cells. Nor will they allow the first young one to whom they grant freedom to touch the rest. Huber illustrates this subject beautifully. Suppose an old queen to have left a very populous hive, as described, with a swarm—'After the departure of the colony, the remaining workers set another queen at liberty, and treat her with equal indifference as the first. They drive her from the royal cells; she also, perpetually harassed, becomes agitated, departs, and carries a new swarm along with her. In a populous hive, this scene is repeated three or four times during spring. The number of bees being then so much reduced, they are no longer capable of preserving a strict watch over the royal cells; several females are therefore enabled to leave their confinement at once; they seek each other, fight, and the queen at last victorious reigns peaceably over the republic.

'The longest intervals we have observed between the departure of each natural swarm have been from seven to nine days. This is the time that usually elapses from the period of the first colony being led out by the old queen until the next swarm is conducted by the first young queen set at liberty. The interval between the second and third is still shorter; and the fourth sometimes departs on the day after the third. In hives left to themselves, fifteen or eighteen days are usually sufficient for the throwing of the four swarms, if the weather continues favourable, as I shall explain.

'A swarm is never seen except in a fine day, or, to speak more correctly, at a time of the day when the sun shines and the air is calm. Sometimes we have observed all the precursors of swarming—disorder and agitation—but a cloud passed before the sun, and tranquillity was restored; the bees thought no more of swarming. An hour afterwards, the sun having again appeared, the tumult was renewed: it rapidly augmented, and the swarm departed.

'Bees generally seem much alarmed at the prospect of bad weather. While ranging in the fields, the passing of a cloud before the sun induces them precipitately to return. I am led to think that they are disquieted by the sudden diminution of light. For if the sky is

uniformly obscured, and there is no sudden alteration in clearness, or in the clouds dispelling, they proceed to the fields for their ordinary collections, and the first drops of a gentle shower do not make them return with much precipitation.

'I am persuaded that the necessity of a fine day for swarming is one reason that has induced nature to admit of bees protracting the captivity of their young queens in the royal cells. If the young females were at liberty to leave their cradles during those bad days, there would be a plurality of queens in the hive, consequently combats; and victims would fall. Bad weather might continue so long, that all the queens might at once have undergone their last metamorphosis, or attained their liberty. One victorious over the whole would enjoy the throne; and the hive, which should naturally produce several swarms, could give only one. Thus the multiplication of the species would have been left to the chance of rain or fine weather, instead of which, it is rendered independent of either by the wise dispositions of nature. By allowing only a single female to escape at once, a regular and successive formation of swarms is secured. This explanation appears so simple, that it is superfluous to insist further on it.'

Our author adds, that another important circumstance resulting from the captivity of queens is, that they are in a better condition to fly when the bees have given them liberty, and are therefore capable of profiting by the first moment of sunshine to depart at the head of a new colony.

Dangers during Swarming.

The capture of the queen, when a swarm has settled on some bush or tree, is, it should be added, the first step towards lodging a swarm in a new hive. If she be placed in it, with two or three bees, the rest will soon follow. A strong glove will enable any one to handle the bees without risk, as they are less disposed to sting when they are swarming than at other times. It sometimes happens, however, that a swarm may settle on the person of any individual who may be near, in which case presence of mind is absolutely necessary for the preservation of life. The following anecdote, related by Thorley, is strikingly illustrative of what has now been advanced:

'One of my swarms settled among the close-twisted branches of a codling-tree; and not to be got into a hive without help, my maid-servant, being in the garden, offered her assistance to hold the hive while I dislodged the bees. Having never been acquainted with bees, she put a linen cloth over her head and shoulders to guard and secure her from their swords. A few of the bees fell into the hive, some upon the ground, but the main body upon the cloth which covered her upper garments. I took the hive out of her hands, when she said that the bees had got under the covering, and were crowding up towards her breast and face, which put her in a trembling posture. When I perceived the veil was of no further service, she gave me leave to remove it. This done, a most affecting spectacle was presented, filling me with the deepest distress and concern, as I thought myself the unhappy instrument of drawing her into so imminent hazard of her life. Had she enraged them, all resistance had been vain, and nothing less than her life would have atoned for the offence. I used all the arguments I could think of, begging her, with all the earnestness in my power, to stand her ground, and keep her present posture. The bees had now got in a great body upon her breast, about her neck, and up to her chin, and I began to search among them for their queen. I immediately seized her, taking her from among the crowd, along with some of the commoners, and put them together into the hive. Here I watched her for some time; and as I did not observe that she came out, I conceived that the whole body would quickly abandon their settlement; but instead of that, I soon observed them gathering closer together, without the least signal for departing. Upon this I immediately reflected that either there must be another sovereign, or that the same was returned. I directly commenced a second search, and in a short time, with a most agreeable surprise, found a second, or the same. She strove, by entering further into the crowd, to escape me; but I reconducted her, with a great number of the populace, into the hive. And now the perilous scene began to change to one infinitely more pleasing and agreeable. The bees, missing their queen, began to dislodge and repair to the hive, crowding into it in multitudes, and in the greatest hurry imaginable; and in the space of two or three minutes, the maid had not one single bee about her, neither had she received so much as one sting, a small number of which would quickly have stopped her breath.'

ARTIFICIAL MANAGEMENT—THE APIARY.

The artificial management of the hive forms, in some measure, a distinct branch of the present subject. In the

first place, the local situation of an apiary, or accumulation of bee-hives, has been held of especial consequence.

Site of Apiaries.

The hives must be sheltered in a particular manner from the action of high winds. A wall or hedge is not sufficient to yield the requisite protection; houses or lofty trees are necessary to insure it. The reason of this is, that the bees, returning homewards, require a calm air at a considerable height above their dwellings, otherwise, when they attempt to alight, they are dashed to the ground and killed, their exhausted strength disabling them from coping with a wind of any force. A low position, enclosed with woods, suits them best. Bees drink much, and a fountain or brook is essential to them; deep pools or cisterns very often cause their death by drowning. Shallow troughs, filled with moss or floating wood, are recommended as a substitute for shallow rills. It is an error, according to the experienced bee-keeper De Gelieu, to suppose that hives should be placed full in the sun. Bees, he says, live and thrive in shady places of moderate and uniform temperature; hence their partiality for forests. Besides, exposure to all the extremes of the solar heat melts and spoils the honey. In fine, if exposure to the sun be beneficial at all, that exposure should last only for a comparatively short time, or from about ten o'clock till noon. Hives should not be placed on upper floors, on account of the increased danger from wind. At the same time, a bee-house ought to be so made as to cause a free passage of air, though not of strong currents, at all periods, with openings both anteriorly and posteriorly. A covered shed or veranda is perhaps the best form of a bee-house, yielding both a shade from the heat and shelter from the wet. Where hives are simply placed on open stands, these should be about sixteen inches from the ground, and each three or four feet apart. Shifting

is condemned by almost all observers, as very hurtful to the bees. Quiet is also necessary to their successful operations; and it has been found that they do not thrive well in the neighbourhood of smithies, mills, steam-engines, and the like, partly, we believe, on account of the noise, and partly owing to the smells emitted from such works.

As to the district of country, that of course will always be preferable which yields such vegetable productions as the insect can turn to account. 'Large heaths, sheltered with woods,' says the *Naturalist's Library*, 'are extremely productive of honey, as the wild thyme and other flowering plants with which they abound are not cut down by the scythe; and the heath itself remains in bloom till late in the season. The plane-tree, the whole willow tribe, the furze or whin, the broom, especially the Spanish kind, furnish a rich store both of honey and farina. Bees do not feed indiscriminately on every species of flowers; several of the most splendid and odoriferous are wholly neglected by them, while they select others, the flowers of which are extremely small, and not apparently possessed of any valuable qualities. Moreover, they give a decided preference to those spots where a *great quantity* of their favourite flowers grow together. On the continent, fields of buckwheat afford a copious supply, though the honey extracted from it is of a coarser kind; and in our own country, the white clover will, in fine weather, be found thronged with them, while scattered plants that afford more honey are neglected. When a variety of bee-flowers flourish in the same field, it is said they will first collect from those which furnish the best honey; if, for example, several kinds of thyme grow together, they prefer the lemon variety, which is of a sweeter and richer fragrance.

'But while mainly depending, as they must always do, on the natural products of the country, the bee-master will do well to supply his favourites with such flowers, &c., as are not found growing spontaneously in his neighbourhood. In addition to the gooseberry, currant, and raspberry bushes, and the several orchard trees, the flower-borders in his garden should be well stocked with snow-drops, crocuses, wall-flower, and, above all, the mignonette, which affords honey of the richest flavour, and which continues flowering till the near approach of winter. The rich melliferous blossoms of the *Buddlea globosa*, too, the bees are very fond of; and some of the *Cacalia* tribe afford an ample store. "The *Cacalea suaveolens*," says Darwin, "produces so much honey, that on some days it may be smelt at a great distance from the plant. I remember once counting on one of these plants above two hundred painted butterflies, which gave it the additional appearance of being covered with additional flowers." Besides these, the plants of borage and viper's bugloss yield a very considerable quantity of the rich liquid. The former is eagerly resorted to by the bees; it is an annual, and blossoms during the whole season, till destroyed by the frost. In cold and showery weather, the bees feed on it in preference to every other plant, owing to its flowers being pendulous. The bugloss appears as a troublesome weed among corn, and grows on dry soils in great profusion; it is a biennial plant. Turnips, particularly the early garden kind, should be sown, and allowed to remain in their beds during the winter; and they will in consequence, by their early flowering, afford a seasonable supply of farina, and also a small portion of honey early in spring. The whole cabbage tribe also may be made to contribute their share; and mustard, when sown in successive crops, will continue to blossom for many weeks together.'

Hives.

The important question of the size, form, and materials of the hive, or artificial habitation, has of course received much attention. Whatever be the form adopted, it is found that bees accommodate their labours to it, and fashion their combs of honey accordingly.

Straw hives, of which a sketch is given in the preceding page, are those most commonly used in cottage-gardens; and being easily and cheaply constructed, they still maintain their place, though much better habitations could be suggested. They are of a roundish form, ordinarily measuring about twelve inches deep and nine inches wide in the lower part. Made of unbroken rye straw, or any other straw of a strong and elastic fibre, and well bound, they will, if tolerably well sheltered, last many years. It is customary to place sticks across the interior, from an idea that such are necessary for supporting the combs; but Mr Taylor, in his *Bee-keeper's Manual*, combats this opinion. 'The sticks,' observes that intelligent writer, 'are only an annoyance to the bees; and there is little fear of the combs falling, except in very deep hives: at anyrate, it may be prevented by contracting the lower part a little. The best way of doing this is by working a wooden hoop inside the bottom band of the hive, as recommended by Dr Bevan, who says, "it should be perforated through its whole course, and the perforations made in an oblique direction, so distant from each other as to cause all the stitches of the hive to range in a uniform manner." The hoop gives greater stability to the hive, preserves the lower edge from decay, and affords facility in moving it. I advise a circular piece of wood (turned with a groove at the edge to retain it in its place) to be worked into the crown, having through it an inch and a half hole. With a little ingenuity, the bees may be fed through this opening—a better method than the ordinary one at the bottom of a hive. A piece of wood or tin will commonly cover the hole; but at times, and especially in winter, it may be used for the purpose of ventilation, and allowing escape to the impure air of the hive. In this case, a bit of perforated tin or zinc should be placed over it, which, when stopped up by the bees, can be replaced by a clean one. An earthen pan is a common cover to a straw hive, and this may be slightly raised by wedges on the four sides, to permit a small space underneath. Of whatever material the outer covering consists, it must project so far on all sides as to protect the hive from moisture. This cannot be too much guarded against; and whether of wood or straw, hives ought to be well painted at the beginning, and periodically afterwards.'

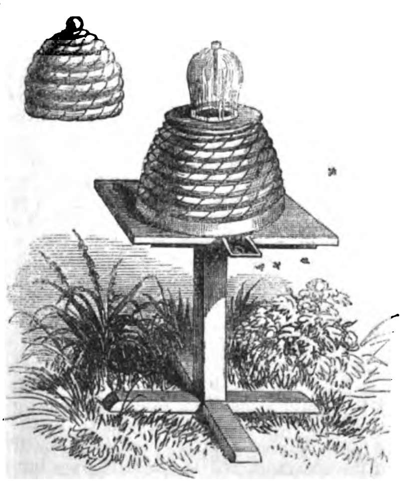
Wooden hives are superior to those made of straw, the square shape being better adapted for the deposit of combs than the round form. Mr Taylor's observations may be likewise quoted on this important point. 'It matters not much of what wood the boxes are made, provided it is sound, thoroughly seasoned, and well put together. Different opinions are entertained as to the best size of bee-boxes, but I think that much must depend on the number of bees they are to contain, and on the honey locality; there must also be a reference to the proposed mode of working them; for where no swarming is permitted, a larger hive may be advantageously used. A good size is twelve inches square and nine inches deep within; the thickness throughout being not less than an inch. The top of the box ought to project on all sides nearly three-quarters of an inch, for better protection and appearance, and as affording convenience for lifting. On the top, a two-inch hole should be cut in the centre, for placing a bell-glass, and for the purpose of feeding; and another hole, to receive a ventilator, may be made near the back window, that position being better for inspection, and less in the way of the bees, than the centre of the hive, which is, or ought to be, the seat of breeding, and should not be disturbed. A window may be placed at the back and front, five inches high, and six or seven inches wide. The best and neatest way of securing the windows that I have seen, is by a sliding shutter of zinc.'

To these explanations it should be added, that the

hive of either form must be placed on a clean wooden floor or board; and if there be several hives together, each should have its own separate floor. Do not cement the hives to the board, that being a duty which the bees will themselves perform; all that may be given is a slight luting of clay, or any easily removable material. The entrance to the hive requires to be small, a little larger than a shilling, but rather wider than deep, and ought to be at the lower edge of the hive, on the side which is exposed. Numberless have been the plans invented to enlarge hives as may be required, both to permit of the greater accumulation of honey, and to render swarming unnecessary. Caps or hoods are the simplest of these inventions. In order to use caps, hives must have a stoppered hole at the top. A small additional hive, of light structure, is placed over this at the proper time, the stopper being removed. This serves as a second magazine for honey. Storied hives are merely hives made originally with one or two stories, for the same end. Wildman's hive, the Grecian hive, and Lombard's hive, are specimens of hives made on this principle. Collateral hives again, such as Nutt's, effect the same ends by being placed side by side, and giving increased accommodation, when necessary, either for swarms or stores.

Use of Caps.—It will be observed from these quotations, that experienced apiarians, who work on a large scale, now employ for the most part hives so contrived as to remedy all the inconveniences resulting from the straggling of swarms and the old custom of killing by brimstone. As the use of single straw hives, however, formed upon the simplest plan, still prevails among those who have but one or two hives in all, the cap may be regarded as the easiest means of affording enlarged accommodation in such cases, and the mode of taking away the honey from it is very plain and easy. It is only necessary to remove the cap, invert it, and cover it with a handkerchief, leaving a little opening on one side. A few taps will cause the bees to quit the cap and return to the hive, after which the honey can of course be readily removed. This may be done frequently in the same season. De Gelieu mentions, that in one season he drew from one of his straw hives that did not swarm seventy-two pounds of fine honey-comb, by merely emptying the caps as they were filled.

One of the cheapest and simplest forms of the capped straw hive is the Improved Cottage-hive, exhibited in



Milton's Improved Cottage-hive.

the Crystal Palace, in 1851, by Mr Milton, and which received a prize medal. It is simply a straw hive of the usual dome-shape, with a wooden hoop round the bottom. The projecting landing-place is sloping and sunk, so as to form an entrance without cutting the edge of the hive. An opening of two inches diameter is left in the top of the hive, and over this is fastened a flat board, not so large as the bottom diameter of the hive, with a similar aperture. The empty space between the top of the hive and the board is filled up with cement or putty. The cap is a smaller hive, adapted to stand on this board, and may be used alone, or to cover a bell-glass. The hole in the board is kept closed by a bung until the bees give indications of swarming, or of having filled the hive; the bung is then withdrawn, and the bees ascend and fill the glass, or the small hive with pure honey. When it is filled, a knife is passed below to detach any combs that may be adhering to the board, and it is then removed, and another cap put in its place. The bell-glass is represented in the cut with an aperture at top, through which a perforated zinc tube descends, for the purpose of ventilation.

Union of Swarms.

It is strongly recommended by experienced men, that swarms should be more often united than they are. Five thousand bees are estimated to weigh a pound; and, according to most bee-keepers, a swarm ought to weigh nearly four pounds. As a hive often casts off successive colonies, each far below this weight, it then becomes proper to unite two or more of them; seeing that one strong population supports itself better, and is incomparably more profitable, than several feeble colonies, which must be frequently in want of assistance. To those who keep bees on a small and cheap scale, convenience also dictates the junction of swarms in such cases. De Gelieu thus describes his mode of practice: 'When two small swarms come off the same day, I gather them separately, and leave them at the foot of the tree or bush on which they have alighted. Towards evening, I spread a table-cloth on the ground, on which, by a smart and sudden movement, I shake all the bees out of one of the hives, and immediately take the other and place it gently over the bees that are heaped together on the cloth, and they instantly ascend into it, flapping their wings, and join those which, not having been disturbed, are quiet in their new abode. Early next morning, I remove this newly united hive to the place it is destined to occupy. This doubled population works with double success, and in the most perfect harmony; and generally becomes a powerful colony, from which a great profit is derived. Two feeble swarms may be united after the same manner, although one of them may have come off some days later than the other, and the first may have constructed combs; taking care, however, not to make the first one enter the second, but the second the first, as the bees will ascend more readily to join those that have already begun to make honey and to hatch brood; and next day they will proceed together with increased ardour with the work which the first had already begun, and which will now advance more rapidly from the increase of the labourers. It is to be understood that, after this union, the hive should be placed early next morning in the same place where the oldest of the swarms has already passed some days.' On many occasions, the circumstance of two queens passing out at once, is the cause of a colony going off in two halves, and the removal of one of the queens is necessary, to facilitate their cordial junction into one community.

Besides the union of young swarms, it is often advisable to reunite weak swarms with their parent stocks, to unite weak stocks with each other, or even to add to some weak community a portion of one more numerous and healthy. In either case the object is the same—namely, to obtain well-filled, strong, and consequently more active hives. The three usual modes—we abridge partly from Bagster—by which union has been attempted, and, indeed, their advocates say accomplished,

are—fuming them, immersing them in water, and aspersing them with sugared or honeyed ale. To these we may add a fourth—namely, operating upon their fears, by confining them for a time, and then alarming them by drumming smartly upon the outside of their domicile. It was operating on their fears that enabled Wildman to perform such extraordinary feats with bees. When under a strong impression of fear, says he, they are rendered subservient to our wills to such a degree as to remain long attached to any place they afterwards settle upon, and will become so mild and tractable, as to bear any handling which does not hurt them, without the least show of resentment.

The neatest and most scientific mode with which we are acquainted of uniting weak families together in harmony, was invented by the Rev. Richard Walond, whose experience in the management of bees, for nearly half a century, entitles his opinions concerning them to great respect. His theory and practice upon this subject are as follows:—'Bees,' says he, 'emit a peculiar odour, and it is by no means improbable that every family of bees emits an odour peculiar to itself; if so, as their vision seems to be imperfect, and their smell acute, it may be by this distinctive and peculiar odour that they are enabled to discriminate betwixt the individuals of their own family and those of a stranger hive. Upon this supposition, if the odours of two separate stocks or swarms can be so blended as to make them completely merge into each other, there will then probably be no difficulty in effecting the union of any two families that it may be desirable to unite.' To accomplish this end, therefore, Mr Walond had recourse to a very ingenious contrivance: he procured a plate of tin, the size of a divider, and thickly perforated with holes, about the size of those in a coarse nutmeg-grater. Having confined, in their respective hives or boxes, the two families to be united, and placed them over each other, with only a divider between them, he introduced his perforated tin plate upon the divider, which was then withdrawn. Immediately the bees began to cluster with hostile intentions, one family clinging to the upper, the other to the under side of the perforated plate; when, after remaining in this state for about twenty-four hours, they had so far communicated to each other their respective effluvia, and so completely commixed were the odours in both hives, that on withdrawing the perforated plate, the bees mingled together as one family: no disturbance was excited, but such as arose from the presence of two queens, the custom being always in such case to dethrone one of them. According to Huber, this is effected by single combat between the queens. Keys has observed that these incorporations seldom turn to account unless they be effected in summer; and when it is considered that the principal gathering months are May and June—excepting in those neighbourhoods that abound in lime, sycamore, and other trees that are apt to be affected with honey-dew—we cannot of course expect them to be very successful.

This plan of the Rev. Richard Walond is very ingenious, and unquestionably, on his authority, proves our position—that smell is one of the senses used by the bees to detect a stranger—and leads us to doubt the authenticity of accounts which state that the system of union by means of driving has been uniformly successful. Our aim, however, is not to condemn, but to shew that fumigation is the easiest and surest operation. The plan is as follows: In autumn, three or four fuzz-balls or puff-balls—a kind of fungus growing in the meadows, and commonly called the 'Devil's Snuff-box'—must be pulled before they are fully ripe. These must be thoroughly dried in an oven, and kept dry till wanted. A round box, made of thick tin, without any solder, must be provided. This box must be about two inches in diameter, and an inch and a half deep, with a conical movable top, about an inch and a half high, perforated with holes. The bottom must also have three holes in it. With this box, and a piece of a fuzz-ball about the size of a hen's egg, in readiness, the operator commences by fixing an empty hive, of the same size as that from which he intends to take the bees, securely, in an inverted position, in a pail or some other convenient utensil. A sharp-pointed stick having been stuck into the empty hive, so as to stand upright within it, the box is fixed thereupon by inserting the stick into one of the holes in its bottom. The piece of fuzz-ball is then lighted and put in the box, over which the conical lid is placed. The hive from which the bees are to be taken is then placed over the empty hive and the burning fungus. To keep all close, a wet cloth is put round the place where the two hives join. In a minute or two, the bees may be heard dropping heavily into the empty hive, where they lie stupified. After a short lapse of time, the full hive may be tapped, to cause the bees to fall faster. On removing the upper hive, the bees from it will all be found lying quiet at the bottom of the lower one. The queen may be taken from them and placed under a glass with a little honey on a small piece of comb. The stupified bees must then be sprinkled freely with a thick sirup made of sugar and ale boiled together. The hive containing the bees with which it is intended to unite the stupified bees, must now be placed on the top of that containing the latter, just as the hive was from which they have dropped. A cloth must be closely fastened round the two hives, so as to prevent any of the bees from escaping. The hives in this position must be put aside, where they will not be likely to be thrown down or disturbed. The bees in the upper hive, attracted by the scent of the sirup, go down and begin to lick the sprinkled bees clean. The latter gradually revive, and all get mingled together, and ascend quietly in company to the upper hive, where they dwell as if they had always been one family. The two hives should be left undisturbed for twenty-four or thirty hours, at the end of which the upper hive is to be removed and placed immediately on the spot from whence it was taken. The object of taking the queen away is to avoid all risk of disagreement. It is, however, recommended to preserve her as long as she will live, lest any accident should happen to the sovereign of the other community.

Summer Management of Bees.

The feeding of bees at different seasons is an important point to the bee-keeper. In summer they feed themselves, and of course a good supply of the requisite material is then essential to their well-doing. The most highly cultivated districts are not so favourable to bees as those in which wild heaths, commons, and woods prevail; or where white clover, saintfoin, buckwheat, mustard, and cole-seed, are produced in abundance. Bee-keepers, however, may do something to further the supply of summer food by growing near their apiaries a selection of such plants as we have recommended under a previous section. But on the natural products of the country, generally speaking, bees must rely for summer food, if the weather be such as to permit of their gathering it. Should a succession of coarse bad weather occur, however, at the beginning of summer, and particularly after a swarm has entered a new hive, most apiarians think it essentially necessary to give honey, or a sirup of sugar and water, to the newly hived stock. If no proper brook or fount be at hand, water should always form a part of the summer provision. The bees being at full work in this season, the door of the hive should be opened to its whole extent, and not closed, as is more or less requisite at other times. In the hives formed upon improved plans, ventilators constitute a part of the apparatus, and thermometers are introduced to regulate their use. Though these are valuable adjuncts certainly, they are not indispensable, seeing that the bees, as already mentioned, contrive to ventilate to some extent for themselves. Where artificial ventilation can be effected, it is recommended that the temperature

should be maintained at from 65 to 80 degrees of Fahrenheit. It is recommended, on evenings when the moths are numerous, to place a small grating before the hive; and it will also be advisable to destroy any wasps, spiders, earwigs, or other insects which may settle near the hives.

Autumnal Management.

The autumnal period has long been the most calamitous for bees, not through the injuries of enemies or weather, but from the improper management of bee-keepers. After the carcasses of the drones, strewn in multitudes before the hive, have indicated that, with the beginning of August, has come the close of the rich honey season, the bee-keeper deems it time to take from the hive the reward of his care and attention. The use of storied hives or extra boxes renders it easy to take away a portion of honey early in the season, and this is called *virgin honey*. Even with a common straw-hive, it has been found possible to take away the honey, and retain the bees in the hive. Wildman, the famous experimenter on bees, recommended that the hive should be taken into a dark room, and there struck repeatedly till the bees are forced to ascend into an empty hive. The combs are then cut out with a thin knife, and the bees finally returned to the old hive. But this plan is seldom pursued, being at once dangerous and destructive to the brood combs.

It is generally reckoned advantageous to change the pasturage for a week or two before taking the honey-harvest. About mid-autumn, the ordinary food of bees begins to fail, and their stock of honey to decrease daily. By a removal of three weeks to a heathy district, a hive not only loses nothing, but frequently gains as much as ten or twelve pounds of honey in ordinarily favourable circumstances. So well is this known by bee-keepers near Edinburgh, that one shepherd on the heathy Pentland Hills receives in charge several scores of hives annually, for the heath-feeding.

Honey-harvest.

After the autumnal accession of honey has been obtained, and the bees have been brought home again, the question comes to be, in what manner the harvest should be reaped. By partially depriving each of a portion of comb, and leaving some for food? By suffocating one half the communities, taking their entire honey, and leaving the other hives with their honey untouched, to serve as stock? Or, finally, by removing the bees from one half the hives to the other half, forming united stocks, and acquiring all the honey of the evacuated ones? These three plans are known by the several names of *partial deprivation*—commonly and most easily practised with improved hives, as already described—*suffocation*, and *union of stocks*. 'Partial deprivation,' says the *Naturalist's Library*, 'consists in appropriating early in the season a portion of the stores. In preparing prospectively for thus sharing in the products of the hive, the cultivator who pursues the storifying system, immediately after the swarming season is over, adds another story or box to the two of which his hive consists, placing it undermost, or, as it is called by some bee-masters, *nadiring*. The brood combs contained in the uppermost story will, as the young bees are hatched, be quickly filled with honey, and may be removed about the beginning of August. The top cover is then replaced on the next story in position, which was originally the lower, and is now the upper. In ordinary seasons, the bees will have ample time to lay in sufficient food for winter and spring use, after the abstraction of this portion of their stores. As the combs of the upper box are frequently found adhering by their lower extremities to the bars of the next, it will be necessary before removal to separate them by means of a very thin long-bladed knife, or a fine wire drawn through the hive at the point of junction. The operator will next expel the bees from this box or story, by lifting the top cover, and blowing in a little smoke, which will cause the inhabitants to retreat quickly to the lower regions. The box may be then taken away, without the operator running the risk of the slightest annoyance. The honey found in this removed box will not be all honey of the current season, and consequently is not so delicately fine. It is also sometimes found mixed with, or rather deposited above a layer of farina. Should it be wished, therefore, to obtain a supply free from these impurities, the empty story which is added may be placed *above*, instead of *below* the original stock, and the honey will thus be of a superior kind. This mode of operating is called *super*-ing, in contradistinction to *nadir*-ing; and we understand that Dr Bevan practises the latter only with young swarms, and the former with those of preceding years.

'Partial deprivation has never yet become general, because it is liable to frequent failure, even in improved hives, and because the full benefit is not derived from it at the very commencement of the system. The liability to failure, the first of the objections stated, is owing in most instances not to the *mode*, but to the *period* of the operation. According to the too common practice of those who are friendly to deprivation, a portion of honey is abstracted from the hives about the beginning or middle of September; and the owner compliments himself on his moderation in being content with a part instead of the whole, and on his humanity in saving the lives of his industrious favourites; while in nine instances out of ten he finds, on the arrival of March, that his moderation and humanity have been altogether unavailing, and that he has saved them from a violent death by suffocation, only to expose them to the more tardy, but not less cruel death by starvation. Whereas if deprivation takes place soon after the swarming season, as already recommended, and is managed with discretion, the issue will be very different, and ultimately more profitable to the owner, than the almost universally practised mode by suffocation, which is too well known to need description. The latter system may yield a greater return in proportion to the hives operated upon; but in the former there is a much greater number of hives available. For example, suppose two apiaries, each containing five stock hives at the end of July, exclusive of as many swarms recently thrown. The owner of the one, practising the depriving system, takes from each of his stocks 10 pounds of honey, making an amount of 50 pounds as his honey-harvest. The owner of the other, an abettor of suffocation, proceeds in September to smoke his five old hives, and receives from each 25 pounds of honey, making an amount of 125 pounds as his honey-harvest—between two and three times the quantity of the other. In the following year, the depriver has his five old-stock hives, and the five swarms now become stocks also; from the whole ten he now takes 100 pounds of honey, while at the same time his apiary is augmented by the addition of ten new swarms, making twenty for the following year; while his rival possesses only his former number of five, yielding 125 pounds. In the next year—that is, two years from the commencement of the comparative trial—the depriver has twenty stock hives, yielding 200 pounds, and so on by a geometrical ratio; while the other remains at his original 125 pounds. This calculation is made on the supposition that each owner takes but one swarm from each stock, and without making any allowance for losses and failures which will affect the produce of both in honey and bees, but to which both are liable.'

The writer of the treatise now quoted from, proceeds to point out the advantages of the humane principle of sparing the lives of these useful insects. 'It is pitiable to reflect, that the small degree of additional trouble required in uniting them, should prove so effectual an obstacle to this conservative practice. Yet the operation with each hive so treated need not occupy

more than fifteen or twenty minutes. In the evening, when all are quiet, turn up the hive which is to be operated upon, fixing it in a chair from which the stuffed bottom has been removed; place an empty hive above it, wrap a cloth round the point of junction, to prevent the bees from coming out and annoying the operator; then, with a short stick or stone in each hand, beat round the sides, but *gently*, for fear of loosening the combs. In five minutes, the panic-struck insects will hastily mount into the empty hive, with a loud humming noise, expressive of their trepidation. The hives are then separated—that containing the bees is placed on its usual pedestal, and the other containing the honey is carried off. The union is next to be effected. Turn up the stock hive, which is to receive the addition to its population; with a bunch of feathers, or a small watering-pan, such as is used for watering flower-beds, drench them with a solution of ale and sugar, or water and sugar, made a little warm. Do the same to the expelled bees; and then, placing these last over the stock, mouth to mouth, a smart rap on the top of the hive will drive them down among the bees and combs of the undermost hive. Place this last on its pedestal, and the operation is completed. The strong flavour of the solution will prevent them from distinguishing between friend and stranger; and their first movement, after recovering from their panic, will be to lick the liquid from one another's bodies. This mode of operating is applicable to all kinds of hives.' (See previous section on the Union of Swarms.) With regard to the two queens, one would assuredly kill the other in a very short time; but the best way is to remove one of them before union.

One argument employed by advocates of the plan of suffocation by introducing the fumes of brimstone or other noxious effluvia is, that by the union of stocks you have an immense number of mouths to feed, of which the killing plan relieves you. Only inexperienced bee-keepers, however, could use this reasoning, De Gelieu having discovered the remarkable fact, that the increase of numbers in the winter hives is far from producing a proportionate increase of consumption. From fifteen to twenty pounds of honey, or from three to four pots, are requisite for the winter maintenance of a single hive of ordinary strength, with which the plan of union has not been practised. De Gelieu placed such a hive, with such a store, beside one into which three full communities had been introduced; and he found, on weighing the latter in the spring, that its inhabitants had scarcely used one pound of honey more than those of the single-stocked hive. The experimenter even went further. To a hive already amply stocked, he added the swarms of *four* other hives, and found, on weighing it in the spring, that 'the total diminution of honey did not exceed three pounds more than took place in ordinary single hives.' Had they not been thus united, he says, each of these stocks would have cost him much more honey than they were worth, and indeed the most of them 'would to a certainty have perished.' The cause of this strange fact, by which nature seems to point to the plan of autumnal unions as the best possible for both bees and bee-keepers, is yet unknown.

The combs, by whatever process procured, should be deprived of the honey at once, while a natural warmth remains in them. Various kinds of drainers have been used for separating the honey, and keeping it as much as possible from the external air. The honey which runs off naturally without breaking down the combs, and passes through muslin, is held to be the finest. A second kind is procured by cutting the combs in pieces, and letting the honey pass through a drainer, under exposure to a gentle heat. A third quality is procured by subsequently putting the combs in a vessel placed on a fire; the product, strained through canvas, is used in feeding bees. The separated wax of the combs is introduced into a woollen bag, firmly tied at the mouth, and put into boiling water. The pure wax oozes through, and is skimmed off the surface, where it floats. It is then to be allowed to cool slowly. The best honey is supposed to be that formed from heath. The famous bees of Hymettus were nourished by that plant.

Honey is used as a condiment at the table, and is also employed in medicine. Its value is rarely under 2s. a pound. In Britain alone, about £120,000 is annually spent for foreign supply; and if we add to this a large home production, and consider that in other countries the article is even more liberally made use of, we shall arrive at some conception of the economical value of the bee. But it is not the honey alone; we import 10,000 hundredweights of wax each year; and when we state that the price varies from £5 to £10, 10s. a hundredweight, it will be seen that its value is all but equivalent to that of honey.

Winter and Spring Management.

In winter and early spring, bees require to be tended with great care. In the case of those hives which have been entirely deprived of their honey, systematic feeding is of course indispensable in winter; but few bee-keepers of any experience ever willingly follow any other plan than that of leaving to bees a winter supply of their own produce. Some bee-keepers remove their hives into the house in winter; but this seems an unwise practice, as the bees must then be kept continually in confinement. Though the door of the hive should be carefully narrowed or shut up in very cold weather, at which time every bee that issues perishes, yet advantage should be taken of every fine day to let them abroad. On this point, however, great difference of opinion exists—many contending that the bee naturally becomes torpid in winter, object to their exposure to sunshine altogether, and for that purpose recommend screens and coverings. One thing is certain, that a moderate degree of warmth is necessary, and that this warmth should be as equable as possible; while at the same time there should be the most thorough precautions against damp. It is damp more than cold which kills our hives in winter; and he who protects them from cold and wet by a thorough covering of straw, fern, flax refuse, or the like, plastered over with Roman cement, is sure to have the healthiest apiary.

Proceeding on the 'dormancy' theory, a singular device for winter preservation has been resorted to by some bee-masters—namely, *burying the hives*. When this is to be attempted, the hive should be buried in a cool, dry, shady place, among leaves about a foot deep, and the interment should be performed during the first or second week of November. Mr Briggs, who first made public this device, records the following experiments:—'A friend in the vicinity of Hitchin buried a hive of bees in the first week of November, about a foot deep among dry leaves, &c., and disinterred it in the last week of February, when it was just *two pounds lighter than it was in November, and the bees in a lively and healthy state*. Another person, residing in Leicester, immured a hive of bees in the earth, four feet deep, in the second week in November, and at the end of January it was removed, and weighed *only three ounces less than it did before it was buried*. The above experiments,' adds Mr Briggs, 'are worthy of further attention; and I would recommend that a shed, having a northern aspect, and which is as dry as possible, would be a suitable place for further trials. The principal points by which there might be cause for fear of failure, would, as in other cases, be from dampness, disease for want of fresh air, and attacks from vermin. To prevent the former, I would recommend that the hives be placed on a long frame of wood, covered by a web of closely worked wire, and raised a few inches from the ground, the ends of which should communicate with, and be occasionally opened to, the fresh air. A long tube should also be placed from the hole at the top of each hive to the open air of the shed, from the upper end of which any

dampness might be condensed by bell-glasses, and conveyed away, as already directed. The materials with which the hives are covered and surrounded should consist of dry leaves pressed closely together, or dry and powdered charcoal or cinders, and may be several feet in thickness, to preserve the bees in a cool and torpid state, and at a regular temperature, in which state they should be kept as *dry*, *dark*, and *quiet* as circumstances will permit. As the spring approaches, the winter coverings should be gradually removed, and the hives placed in their summer situations. Small quantities of food should then be supplied as occasion requires, until the gooseberry and currant bushes are in bloom, at which time it may in general be considered that their winter is past.'

Where feeding is necessary, the following rules have been laid down for the management of common hives in winter and early spring:—Bees must be fed only when the weather is fine and warm, to prevent the temperature of the hive from being injured; and a large quantity should never be given at once. The quantity of food which ought to be given to a hive may be calculated in the proportion of two pounds a month; but if the weather be very cold, a less quantity will suffice. When a hive is fed in the spring, it should always be after sunset, when the bees have returned from the fields; otherwise the most disastrous consequences may ensue, from the robberies committed by the bees of other hives. If fed in the morning, it must be before sunrise, and the entrance instantly stopped, to keep out depredators; for as bees leave the hive on the very first appearance of daylight, a later period would prevent the return of those which had left the hive previous to the entrance being secured.

Relative to the substances which are proper for the feeding of bees, many different opinions exist; but the following may be considered among the most beneficial as well as economical articles of diet:—To two quarts of good ale put one pound of moist sugar; boil them until the sugar is wholly dissolved, carefully skimming it; when it is cold, it will be found of the consistency of honey, and it may be given to the bees in the following manner: If the bees are in the plain cottage-hive, an eke of the same diameter as the hive must be provided, and from three to four hands in height. When the sun is set, and the bees have retired, let the hive be gently raised, and the eke placed on the stool; then, having filled a soup-plate with the food, place it in the eke, and put down the hive. To prevent the bees being drowned in the liquid, it is necessary to place some straws over the plate, and over the straws a piece of paper, either thickly perforated or cut into nicks; these nicks, however, must not run parallel with the straws, but either across or diagonally; the entrance must then be closed, and the plate removed on the following morning, when the whole of the liquid will have been transferred to the combs. In order to avoid lifting up the hive for the purpose of feeding, some recently invented hives have a drawer under the bottom board, into which a shallow vessel containing the food is put, access to it being opened for the bees by drawing out a tin slide in the bottom board. The food is covered with a float of thin cork or wood, pierced with holes. In others, the feeding-saucer is placed on the top of the hive, under a bell-glass, and the bees allowed to ascend through an aperture.

Diseases and Enemies of Bees.

Bees, according to the conclusions of De Gelieu, after sixty-four years' experience, have 'no real disease; they are always in good health as long as they are at liberty, and when they are warm enough, and have plenty of food.' In early spring, however, they are found liable to an affection called dysentery, which is known by the marks on the board of dark-coloured evacuations, by the offensive smell, and by the frequent deaths. This disease certainly results, in most cases, from long confinement in a damp and impure air. By lifting the hive to expel the vitiated air, scraping, washing, and drying the board, and removing the dead bodies, the complaint, says Mr Taylor, may soon be remedied even in the most extreme cases. Rosemary, mixed with honey and water, has been recommended as a cure; but the experienced apiarian mentioned, conceives all dietetic remedies to do more harm than good. A little chloride of lime, he suggests, may be used beneficially in washing the board. One point should be noticed here, that exposure to the sun is held decidedly injurious to the hives in winter. This caution is necessary, as bee-keepers, when they suspect dampness, might fall into an error on this score. While on this subject, we may also mention a new remedy, which is said to have been adopted on the continent with success. When dysentery begins to shew itself in the apiary, the bee-keeper prepares a sirup composed of an equal quantity of good wine and sugar, which is administered to the bees in every hive, either by pouring it into the cells, or placing it within the hive in a saucer, or any other shallow vessel.

About the end of spring, another disorder sometimes makes its appearance, which Du Carne de Blangy calls vertigo. This is supposed to be occasioned by the poisonous properties of certain plants on which they feed. The symptoms are manifested by a dizzy manner of flight, by their involuntary startings, falls, and other gestures in attempting to perform their usual operations, or in approaching the hive, and by the lassitude that succeeds these symptoms. This distemper has been hitherto found incurable. Bees, according to the same authority, are liable to a third distemper, the symptoms of which are swelling at the extremities of the antennæ, which become also much inflamed, and of a yellow colour; the head assuming shortly after the same tint, the bees lose their vivacity, and languish till they die, unless a proper remedy be applied. In France, they give them Spanish wine for this disorder. There is still another distemper which sometimes makes its appearance among bees, for which the continental agriculturists administer Spanish wine, as in the former case. This is a kind of pestilence, by which many of the insects are cut off. It happens when the queen-bee has placed the eggs carelessly in the comb, so that the larvæ perish in the cells, or that they are killed by the cold or otherwise, when numbers die and infect the rest. The only attention requisite in this case is to remove the infected combs, perfume the hive with aromatic plants, and give them the wine to sip, as already mentioned, in order to strengthen and restore them from their sickness.

A few hints from Gelieu and others, respecting the chief foes of the bee tribe, may be useful to bee-keepers. The former authority, after observing that the possessors of bees, often from an ignorant excess of care, are among their greatest enemies, says: 'Ants are their least dangerous enemies: true, the bees cannot sting them to death, because they are small and well defended with armour, but they seize hold of them with their teeth, and carry them to a distance. Had they not this means of getting rid of them, their colonies could not exist in the vast forests full of ants' nests, and where they thrive so well, in spite of the horrible massacres that annually take place.

'Moths are little known, and never injurious, in the high valleys, nor on the mountains; but they attack and destroy a vast number of hives in the plains or in the vineyards, where they are a great scourge. Huber discovered that the *Sphinx atropos*, or death's-head moth, was one of the most destructive of this tribe. As soon as a moth has penetrated a weak hive, it establishes itself in a comb, envelops itself in a silken web, multiplies rapidly, consuming the wax, and spreading its destructive galleries from side to side, until, arriving at a certain point, the evil has scarcely a remedy. The only means of saving the colony is to imitate the surgeon, who cuts off a diseased limb to save the other—every

bit of infected comb must be cut out, leaving only those occupied by the bees. The bees must then be liberally fed, by giving them every evening as much honey as will maintain them, until such time as the field-flowers shall again yield a sufficient quantity. Thus, concludes Gelieu, I have preserved hives whose circumstances seemed to be desperate.

'Spiders annoy the hive much. The bees get entangled in their webs, and are not able to extricate themselves. Here cleanliness is the best protection; therefore care should be taken to sweep the webs away from the hive and its avenues as fast as they appear.

'Birds, such as the sparrow, house-lark, and swallow, eat a prodigious quantity of bees, especially in spring, when the trees are in blossom. Poultry, also, that roam about or near the water where the bees go to quench their thirst, gobble up a great many. Fowls should never be permitted in any apiary.

'Mice, especially the red mouse, or *Sorex araneus*, sometimes penetrate a hive in the winter-time, either from the entrance being left too wide, or by gnawing a hole for themselves in the straw. They eat the honey, and even the bees, when clustered together on the side of the hive, in which position they are unable to defend themselves, and scarcely even see the enemy. The most effectual preventive against rats and mice is to place the hive on stands with projecting ledges, and in such a position that they cannot reach it.

'Wasps are also reckoned among the numerous enemies of bees. I have, however, seldom seen a hive destroyed by wasps; although they are larger, stronger, and armed with a formidable sting, and an impenetrable cuirass, they seldom dare enter a well-stocked hive. Once attacked, they soon fall beneath the united efforts of these brave citizens, who sacrifice themselves to defend the place of their nativity. Wasps only appear in great numbers when the fruit is ripening, and then they range unceasingly round the hives, and enter the weak ones, or those of which the too spacious lodging bears no proportion to the number of its inhabitants. There are three ways of providing against the attacks of wasps: the first is, to unite weak hives by doubling or tripling the population, thereby enabling them to defend themselves; the second is, to contract the entrances, as soon as swarming time is over, after the massacre of the drones; and the third is, to destroy with assiduity all the nests of wasps that can be discovered in the neighbourhood.

'Bees are subject also to a peculiar species of *pediculus*, called the bee-louse. Hives that have swarmed more than once, and such as contain but little honey, are most exposed to those troublesome vermin. The hives in this case should be cleared at the furthest once every week, and the stools on which they stand every morning; for the latter are likely to harbour the larvæ and moths, or other insects, as well as the hive. But these obnoxious creatures cannot be entirely extirpated without taking away the infected hive, removing the bees, and cleaning it, before it is restored to the former station. The lice are of a slender shape, or filiform, and of a ferruginous colour, and may be destroyed by strewing tobacco over the bees.

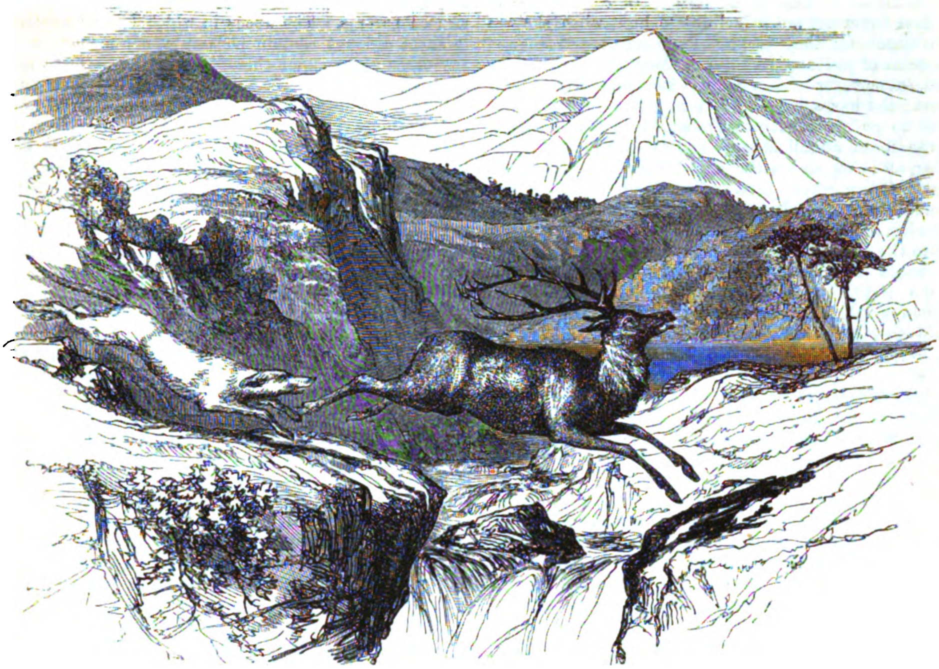
'The bees are continually fighting between themselves, and robbing each other: avarice, not necessity, leads them to do so, it being almost always the strongest and best provisioned hives that pillage the weak ones. When once a bee has been able to introduce itself into a hive, and carry away a load of honey without being arrested, it will return a hundred times the same day; and, making it known to its companions, they will then come in hordes, nor cease their pillage until there is nothing left to take. In one day, the whole of the honey will be carried off, and with a determination which one can scarcely have an idea of without seeing it. This kind of pillage is most frequent in the spring and autumn, and it is easier to prevent than to stop it; and, for this purpose, the entrance of the hives ought to be straitened in proportion to the population.'

BRITISH WILD BEES.

Besides the garden or hive bee, as already mentioned, there are various species of bees, which have never been domesticated by man, though many of them construct hives and produce honey. Of such of these wanderers of the wilds as are indigenous to Britain, the most common is the *humble*-bee (*bombus*), an insect at least double the size of the hive-bee, with a black head and body, having yellow rings crossing the latter anteriorly and superiorly, and white and black rings alternating at the posterior extremity.

On account of their peculiar habits, this and the other wild species are unfitted for domestication. Few of them survive the rigours of winter; but one, a female, that does escape, manages for a season the resuscitation of the breed. Abroad it flies in early summer, and, alone and unaided, sets laboriously to work in constructing its nest, piercing the earth or moss, as its instinct may be, and excavating a small chamber wherein to lay its eggs. It does not make wax and cells for the young. These come to maturity in the cocoons which they spin for themselves in the larva state; and when they emerge, these cocoons form stores for food. The solitary bee feeds alone its earliest progeny, but these soon multiply around it, make more cells, gather honey, and feed the increasing young. Towards the middle or latter part of September, however, the energies of the bees begin to wax fainter, and little further progress is made in adding to the colony, or in collecting honey. Cold and showery days begin, even by this time, to thin the number of the insect population, which are now seen creeping slowly, with damp and heavy wings, upon the stalks and petals of flowers, where they were formerly seen actively buzzing about in search of honey. The stores of the honey-cups have not outlasted the wants of the young unfledged bees, of which they were the proper food; and if the nests be examined now, these cups are found quite empty. The surviving bees by degrees forsake the nest and its furniture, leaving the latter as a prey to mice, beetles, or other animals. To shelter themselves for the winter, they seek out some dry bank, where they penetrate to the depth of eighteen inches or two feet, pushing up the soil behind them, and leaving no visible track by which they have descended. In these situations they are often found by labourers and others while digging; and such people are often greatly puzzled to imagine how the insect can have reached such a depth. Those who have attended to the habits of wild bees can readily fix on the spots where they take refuge.

The experiment of domesticating wild bees has been tried; and it was found that, by removing their nest cautiously in an evening, and placing it in a quiet situation, in a garden or other place where they could be observed, they went on with their works without apparent alarm or interruption. During the whole summer, they continued to prosecute their occupations with the same industry as other bees; but about September, as we have mentioned, the hive began to turn languid, and the numbers which appeared going and coming about the entrance became daily smaller. It was imagined they had taken refuge within the hive; but when this was opened, after all seemed to have ceased their labours, everything was found empty and deserted; there were neither bees nor honey; the stronger and younger insects, no doubt, having gone to make burrows for themselves in the earth, and the older ones having gradually fallen victims to the accidents of approaching winter. Our wild bees, therefore, appear to possess their brief lives but for self-enjoyment, or rather to form one of that order of beings created by the great Author of all, as if for the purpose of leaving no corner of the universe without its utmost allotment of sentient and enjoying existence.



The Chase.

THE DOG—FIELD-SPORTS.

ACCORDING to naturalists, the dog belongs to the family *Canidæ*, which includes the wolf, fox, and jackal. It is generally agreed that the different breeds of the domestic dog are merely *varieties*, and not distinct *species*. But the question as to what was the parent stock, is still undecided; some zoologists hold that the breed is derived from the wolf, others that it is a tamed jackal. Into this and other difficult questions of the natural history of the dog, we refrain from entering, and proceed to make some remarks on

EFFECTS OF TRAINING.

In no case is the fact of animal educability more strikingly demonstrated than in that of the dog. The pointer, setter, springing spaniel, and all that section of dogs, are understood to be descended from one stock—the Spanish pointer—with a slight crossing from the foxhound, for the sake of improving the speed. The original animal may be considered as a record of the primary powers, to which everything else must be regarded as an addition made by human training. Now, the original animal is only gifted by nature with a fine scent for game, and a disposition to make a momentary pause on seeing it, for the purpose of springing upon it. Man has converted this inclination to a temporary pause into a habit of making a full stop, or point, as it is termed; and the animal, instead of gratifying his destructive tendency by springing upon the game, has been trained to be contented with witnessing a vicarious execution by the gun of his master.

It is a mistake to suppose that only the spaniel tribe is capable of serving sportsmen in the capacity of pointers and setters. There are other classes of dogs which perseverance would enable, to a certain extent, to act in the same way. Gervase Markham, who wrote on sports in the sixteenth century, speaks of having seen dogs of the bastard tumbler kind adapted to act as setters, though not so well as those of the spaniel kind. Mr Blaine (*Encyclopædia of Rural Sports*) is of opinion that this power can be cultivated in most dogs. It has even been elicited in another and very different class of animals—the hog. Some years ago, Mr Toomer, gamekeeper to Sir Henry Mildmay, bethought him of teaching a pig to act as a pointer, having been struck by the scenting powers of the animal in its search for palatable roots under ground. He began by allowing a young female pig to accompany his pointers, in their breaking-lessons, to the field. Within a fortnight, to his own surprise, she was able to hunt and point partridges and rabbits. There being an abundance of these creatures near the keeper's lodge, her education advanced rapidly by frequent exercise, and in a few weeks she was able to retrieve game as well as the best pointer. *Slut*, as this extraordinary animal was called, was considered to have a more acute scent than any pointer in the charge of the keeper; and it was a kennel of the highest character. They hunted her principally on moors and heaths; and it often happened, that when left behind, she would come of her own accord and join the pointers. 'She has often stood,' says Daniel, 'a jack-snipe when all the pointers had passed it: she would back the dogs when they pointed, but the dogs refused to back her until spoke to—Toomer's dogs being all trained to make a general halt when the word was given, whether any dog pointed or not, so that she has been frequently standing in

the midst of a field of pointers. In consequence of the dogs being not much inclined to hunt when she was with them—for they dropped their sterns and shewed symptoms of jealousy—she did not very often accompany them, except for the novelty. Her pace was mostly a trot; she was seldom known to gallop, except when called to go out shooting; she would then come home off the forest at full stretch, and be as much elated as a dog at being shewn the gun. She always expressed great pleasure when game, either dead or living, was placed before her. She has frequently stood a single partridge at forty yards' distance, her nose in a direct line to the bird; after standing some considerable time, she would drop like a setter, still keeping her nose in the right direction, and would continue in that position until the game moved: if it took wing, she would come up to the place, and draw slowly after it; and when the bird dropped, she would stand it as before.'

These facts, together with what common observation presents to us in domesticated parrots, black-birds, ravens, magpies, monkeys, &c., place the educability of animals upon a basis, in our opinion, not to be shaken. But the most wonderful thing, and the most convincing part of the proof, remains in the fact of the transmission of *acquired qualities* by animals to progeny. The habit which education has conferred upon the pointer appears in his puppy, which may be seen earnestly standing at chickens and pigeons in a farmyard, before he has ever accompanied his seniors to the field, or received the least instruction. Here only the object is amiss; the act itself is perfect. As may be readily supposed, the puppy of a race of English pointers can be trained to the whole business of the field in one-tenth of the time which the most experienced breaker would require to effect any improvement upon the simple instinct of *the pause* in an original Spanish spaniel. On the subject of the hereditary transmission of acquired qualities by animals, we have some curious information from the venerable naturalist, Mr T. A. Knight, in a communication to the Royal Society in 1807. 'In all animals,' he says, 'this is observable; but in the dog it exists to a wonderful extent; and the offspring appears to inherit not only the passions and propensities, but even the resentments of the family from which it springs. I ascertained that a terrier, whose parents had been in the habit of fighting with polecats, will instantly shew every mark of anger when he first perceives the scent of that animal, though the animal itself be wholly concealed from his sight. A young spaniel brought up with the terriers shewed no marks of emotion at the scent of the polecat, but it pursued a wood-cock, the first time it saw one, with clamour and exultation: and a young pointer, which I am certain had never seen a partridge, stood trembling with anxiety, its eyes fixed and its muscles rigid when conducted into the midst of a covey of those birds. Yet each of those dogs are mere varieties of the same species, and to that species none of these habits are given by nature. The peculiarities of character can therefore be traced to no other source than the acquired habits of the parents, which are inherited by the offspring, and become what I call *instinctive hereditary propensities*.'

It appears from another communication made by Mr Knight to the same society in 1837, that he had then been pursuing investigations on this subject for nearly sixty years. He proceeds in that communication to give a general account of his investigations:—'At the period,' he says, 'at which my experiments commenced, well-bred and well-taught springing spaniels were abundant, and I readily obtained possession of as many as I wanted. I had at first no other object than that of obtaining dogs of great excellence; but within a very short time, some facts came under my observation which very strongly arrested my attention. In several instances, young and wholly inexperienced dogs appeared very nearly as expert in finding wood-cocks as their experienced parents. The woods in which I was accustomed to shoot did not contain pheasants, nor much game of any other kind, and I therefore resolved never to shoot at anything except wood-cocks, conceiving that by so doing the hereditary propensities above mentioned would become more obvious and decided in the young and untaught animals; and I had the satisfaction, in more than one instance, to see some of these find as many wood-cocks, and give tongue as correctly, as the best of my older dogs.

'Wood-cocks are driven in frosty weather, as is well known, to seek their food in springs and rills of unfrozen water; and I found that my old dogs knew about as well as I did the degree of frost which would drive the wood-cocks to such places; and this knowledge proved very troublesome to me, for I could not sufficiently restrain them. I therefore left the old experienced dogs at home, and took only the wholly inexperienced young dogs; but, to my astonishment, some of these, in several instances, confined themselves as closely to the unfrozen grounds as their parents would have done. When I first observed this, I suspected that wood-cocks might have been upon the unfrozen ground during the preceding night; but I could not discover—as I think I should have done had this been the case—any traces of their having been there; and as I could not do so, I was led to conclude that the young dogs were guided by feelings and propensities similar to those of their parents.

'The subjects of my observation in these cases were all the offspring of well-instructed parents, of five or six years old or more; and I thought it not improbable that instinctive hereditary propensities might be stronger in these than in the offspring of very young and inexperienced parents. Experience proved this opinion to be well-founded, and led me to believe that these propensities might be made to cease to exist, and others to be given; and that the same breed of dogs which displayed so strongly a hereditary disposition to hunt after wood-cocks, might be made ultimately to display a similar propensity to hunt after truffles; and it may, I think, be reasonably doubted whether any dog, having the habits and propensities of the springing spaniel, would ever have been known, if the art of shooting birds on the wing had not been acquired.'

GENERAL CHARACTERISTICS OF THE DOG.

The general form and aspect of the dog is too well known to require any description. He has six incisory or cutting teeth in both jaws; beyond which there are, on each side, both above and below, a canine tooth; and still further into the mouth are six cheek-teeth, or molars, in each side of the upper jaw. The first three are sharp and cutting, which Cuvier calls false molars. The next tooth on each side is a carnivorous tooth, furnished with two cutting lobes, beyond which the other two teeth on each side are flat. There are seven cheek-teeth, on both sides, in the under jaw; four of these are false molars, a carnivorous tooth, with the posterior part flat, and behind it two tuberculous teeth. The muzzle is elongated, subject to great variety of length in different varieties. The tongue is smooth and soft; the ears erect in the wild varieties, and in some of the tame ones, but, in the latter kinds, for the most part pendulous. The fore-feet are provided with five toes, and the hind-feet with four toes, furnished with rather longish nails, obtuse at their points, and not retractile. Occasionally a fifth toe occurs on the hind-feet, termed the *dew-claw;* this is generally removed by the sportsman when the animal is young, as its presence is calculated to impede the animal's movements. The dew-claw is regarded as a sign of degeneracy. The females are provided with both inguinal and ventral teats. The pupils of the eyes are circular.

The female goes with young sixty-three days, and

generally produces from three to five at a birth, and sometimes even twelve, which are at first blind, continuing so for from nine days to a fortnight. About the end of two months their faculties begin to develop themselves. They shed their first teeth at the end of six months, which are replaced by others that do not exfoliate. At twenty months, or two years, dogs arrive at their full vigour. The males continue to propagate for nearly their whole lives, while the female discontinues having young ones at about the age of eight or nine years.

The average age to which dogs live is about fourteen years; they frequently, however, live to sixteen, and even have been known to attain the age of twenty years. In their latter days, dogs frequently suffer greatly from decay, and various diseases. They are extremely subject to rheumatism, from their liability to exposure to rain and damp kennels. Until dogs have attained seven or eight years, their teeth are white, smooth, and acutely pointed; but after this age they become yellow-spotted, and their points assume an uneven and jagged appearance. At this time, also, the hair of the muzzle and around the eyes assumes a hoary appearance, and becomes whiter as they increase in years.

The dog is naturally carnivorous; but when domesticated, he does not refuse farinaceous food. He uses grass as a medicine; and drinks by lapping with his long flexible tongue. He does not sensibly perspire by the skin; the superfluous moisture of the body escapes at the mouth by panting, when heated, and by the extraordinary diuretic habits of the animal. The sense of smell is different in different varieties, but in all is sufficiently strong and refined to enable the dog to seek out and follow his master even amidst a crowd. His sense of hearing is also quick. He expresses anger by growling or barking, but also barks when joyful; and shews delight by the wagging of his tail. He exhibits fear by crouching and whining, howls when pained, and droops his tail under reproof. He sleeps very lightly, so as to be awakened by the slightest noise; and during his slumbers he is apt to dream, as is indicated by starting, whining, and short barks.

The most remarkable feature in the character of the dog is his attachment to man. In wild unpeopled countries, dogs are known to live in hordes, and seek their prey like other untamed animals; but brought into connection with human society, the dog leaves his own species without regret, and is only happy when belonging to a master to whom he can be faithful as a friend, servant, or companion. In this condition of domestication his ambition seems to be the desire to please; he is seen to come crouching along, to lay his force, his courage, and all his useful talents, at the feet of his master: he waits his orders, to which he pays implicit obedience: he consults his looks, and a single glance is sufficient to put him in motion: he is more faithful than even the most boasted among men: he is constant in his affections, friendly without interest, and grateful for the slightest favours: much more mindful of benefits received than injuries offered, he is not driven off by unkindness: he still continues humble, submissive, and imploring; his only hope to be serviceable, his only terror to displease: he licks the hand that has just been lifted to strike him, and at last disarms resentment by submissive perseverance.

More docile than man, as Buffon observes, more obedient than any other animal, he is not only instructed in a short time, but he also conforms to the dispositions and manners of those who command him. He takes his tone from the house he inhabits: like the rest of the domestics, he is disdainful among the great, and churlish among clowns. He knows a beggar by his clothes, by his voice, or his gestures, and forbids his approach. When at night the protection of the house is committed to his care, he seems proud of his charge; he continues a watchful sentinel; he goes his rounds, scents strangers at a distance, and gives them a warning of his being upon duty. If they attempt to break in upon his territories, he becomes more fierce, flies at them, threatens, fights, and either conquers alone, or alarms those who have most interest in coming to his assistance; however, when he has conquered, he quietly reposes upon his spoil, and abstains from abusing—thus giving at once a lesson of courage, temperance, and fidelity.

CLASSIFICATION OF VARIETIES.

Cuvier, the eminent French naturalist, formed a classification of dogs, founded on the shape of the head, and length of the jaws and muzzle. These he has separated into three great groups, as follows:—

I. MATINS.—These have a head more or less elongated; the parietal bones insensibly approaching each other, and the condyles of the lower jaw placed in a horizontal line with the upper cheek-teeth.

II. SPANIELS.—The head moderately elongated; the parietal bones do not approach each other above the temples, but diverge and swell out, so as to enlarge the forehead and cavity of the brain. In this group are included all the varieties of dogs which are of the greatest utility to man, and also the most intelligent.

III. DOGUES.—The muzzle more or less shortened; the skull high; the frontal sinuses considerable; the condyle of the lower jaw extending above the line of the upper cheek-teeth. The cranium is smaller in this group than in the two previous, owing to the peculiar formation of the head.

These three groups have, for convenience, been further subdivided into nine sections, which we shall now treat *seriatim*—noticing the different breeds or varieties which have been ranked under each.

I.—Dogs with Lengthened Heads.

SECTION 1.—Half-reclaimed dogs, which hunt in packs.

The *Dingo*, or *Australian Dog*.—The head of this dog is not unlike that of a wolf, on which account Bewick calls it the New South Wales wolf. The muzzle is long and pointed, with short erect ears. He is two feet six inches in length, and about two feet in height. His fur is composed of a mixture of silky and woolly hairs, and is of a deep yellowish-brown colour; and his tail is long and bushy, resembling that of a fox, but generally carried curled over his haunch, and not pendent. The dingo, though naturally ferocious, is easily rendered tolerably tame; and in this state many specimens are now brought to this country. They are not to be trusted, however; and the moment they escape from confinement, all their natural blood-thirsty propensities return. We knew one which, after two years' domestication, happened to slip the chain; and in less than a week, upwards of a score of sheep were destroyed by him in the neighbourhood.

The *Dhole* is the native wild-dog of India, and bears a strong resemblance to the dingo, but without the bushy tail of that species: he is of a uniform bright-red colour. Differently from other dogs which hunt in packs, according to the account given by Captain Williamson, this species always hunts mute, and only utters a soft whispering sound when in high chase, and near his prey. The dhole is exceedingly swift of foot, and soon overtakes most animals which are the objects of his pursuit. It is said they are exceedingly fond of the flesh of the tiger, and that, in consequence, this animal is prevented from propagating to that extent which would soon overrun and lay waste all the countries which it inhabits. This predilection is confirmed by Bishop Heber, who states, upon the authority of the peasants of Khayssa, which borders the frontiers of China, that a tiger is often killed and torn to pieces by the wild dogs, which give tongue like foxhounds or harriers. It is in the unfrequented wilds of the western frontiers of India that the dhole takes up his abode,

lurking amongst the extensive jungles which cover mighty tracts of that territory.

The *Pariah* is the common village-dog of India. He has a small sharp head, with short pricked ears, a slender body, and particularly drawn up about the abdominal region; his chest is deep, his limbs light, and his colour is of a reddish-brown. The native Indians use the pariahs in hunting the tiger and wild-boar. They are very fierce, and follow their game with much avidity and determination.

The *Ekia* is the native dog of Africa, and in all likelihood sprung from the same stock as the dhole. They are said to be of various colours—as black, brown, white, and yellowish. They are eaten by the negroes, who relish them greatly. The African wild-dogs, like those of India, hunt in packs.

The *South American Dog* is not unlike the dingo, and is about the size of the springer, with short and pricked ears, like most other wild-dogs. The hair on his tail is long and bristly; he is of a brownish-gray colour on the back, with sandy-coloured spots on the legs and flanks. In general aspect he greatly resembles the wolf, but is much smaller in size. There is another South American dog called the Alco, of which there are two varieties. The head of the alco is very small, and the ears pendulous, thus differing from almost all other wild-dogs. The back is somewhat curved, and the tail rather short. It is said that the Spaniards found this dog among the natives on the first discovery of America. Herrere says that Columbus found in America many dogs which did not bark. But there is reason to suppose that whatever may have been the original types of the South American dogs, they have been greatly altered by intermixture with the descendants of those introduced at the conquest by the Spaniards.

The *North American Dog.*—We have no very distinct account of this variety, but it is said to resemble the dingo in its pricked ears and general conformation. It is remarkable for the acuteness of its scent, and very expert in the detection of its prey, or animals which it may be trained to pursue.

SECTION 2.—Domesticated dogs, which hunt in packs or singly, principally by the eye, although sometimes by the scent.

The *Irish Greyhound* ranks among the noblest of the canine race: his mien is striking, full of dignity, and his conformation beautiful. In his general shape he bears a strong resemblance to the common greyhound, but is much taller, and more robust. His use in early times was to free the country of wolves and wild-boars, which abounded in England and Ireland; hence he is sometimes termed the 'Irish wolf-dog.' The hair is rough and shaggy, and the colour of these dogs is fawn or pale cinnamon. The Marquis of Sligo is said to have had some of this breed (?), which were of various colours: some were brown and white, and others black and white. The ordinary height of the Irish greyhound is about three feet, although they have been known to reach four feet. Goldsmith, who had seen several of this breed, says they were about four feet high, and as tall as a calf of a year old. The *true* Irish wolf-dog is now extremely rare, if not altogether extinct.

The *Albanian Dog* is about the size of a full-sized mastiff. His hair is very fine and close-set, and of a silky texture, variously clouded with brown; his tail is long and bushy, and carried like that of a Newfoundland dog; his muzzle is pointed, and rather long; his legs are strong and muscular, which fit him well for hunting the wild-boar, in which sport he was much used in ancient times; he was also used in hunting wolves, and in protecting sheepfolds from thieves.

The *French Matin* has an elongated head, and flat above; his ears are erect, and slightly pendulous towards the tips; the hair of a yellowish fawn-colour, with darker, oblique, and parallel indistinct rays traversing the whole of his fur. His height is about two feet, and his length three feet. He is strong, muscular, and active, and very courageous. He evinces great eagerness in hunting the wild-boar and wolf, in which sport he is frequently employed. Pennant thinks this variety is a descendant of the Irish greyhound.

The *Scottish Highland Greyhound* will either hunt in packs or singly. He is an animal of great size and strength, and at the same time very swift of foot. In size he equals, if not excels, the Irish greyhound. His head is long, and the nose sharp; his ears short, somewhat pendulous at the tips; his eyes are brilliant and very penetrating, and half concealed by the long crisped hairs which cover his face and whole body. He is remarkable for the depth of his chest, and tapers gradually towards the loins, which are of great strength, and very muscular; his back is slightly arched; his hind-quarters are powerfully formed, and his limbs strong and straight. The possession of these combined qualities particularly fits him for long endurance in the chase. His usual colour is a reddish sand-colour, mixed with white; his tail is long and shaggy, which he carries high, like the staghound, although not quite so erect. It is this noble dog which was used by the Scottish Highland chieftains in their great hunting-parties, and is supposed to have descended in regular succession from the dogs of Ossian.

The *Russian Greyhound* is nearly as large as the Irish greyhound, resembling him in shape as nearly as possible, but covered with long bushy hair. His general colour is a dark reddish-brown. He is sometimes hunted in small packs, and as frequently single, in which case he not unfrequently will kill a wolf, deer, or wild-boar, without any aid whatever. When used in coursing, he is taken to the field in slips, in the manner practised with greyhounds.

SECTION 3.—Domesticated dogs, which hunt singly, and always by the eye.

The *Gazehound* is a dog the breed of which is now lost. It was hunted in the same manner as the greyhound, and took foxes and hares by running them down. It is said by Bewick that it was employed in stag-hunting, which we think is rather doubtful, as although the stag is an animal of great speed, yet the contest between it and a dog possessing the swiftness of a greyhound would be but very unequal.

The *Greyhound* is the fleetest of all dogs, in consequence of his peculiar conformation. His head is long,

Shepherd's Dog—Scotch and Irish Greyhounds.

tapered, and shaped like that of a snake; his neck long and slender; his ears somewhat erect and pricked, slightly pendulous at their tips: the tail ought to be very

fine, curved and pointed, and the hair on it very short; the chest should be wide and deep; the belly drawn up with strong loins, and with large and prominent hip-muscles. This dog is by no means so intelligent as many other varieties, and he is, in consequence, much less susceptible of education. He has, however, very fine feelings, and seems to be much alive to caresses, which excite him to such a degree, as to produce a quick pulsation of the heart. This may be felt beating against his side with much vigour. He is one of the most elegantly formed of all the canine species.

The *Scotch Greyhound* is formed exactly like the common greyhound, and differs from it merely by being of a larger size, and in the hair being longer and wiry. The general colour is reddish-brown or sandy.

The *Italian Greyhound* is merely a miniature of the common greyhound, being only about half the size of that dog. It has a very fine coat of a silky texture, and is so tender, as to be easily injured by cold or wet. It is used only as a *pet*, being altogether valueless in other respects.

The *Turkish Greyhound* is still smaller than the Italian greyhound, being little more than half its bulk, and is entirely divested of hair, except on the tail, where it is few and scattered. Its usual colour is a blackish lead-colour. It abounds in Turkish towns, where it forms a dreadful nuisance to travellers.

II.—Head less elongated than former Division.

SECTION 4.—Pastoral dogs, or such as are employed in domestic purposes.

The *Shepherd's Dog* is covered with long, flowing, and somewhat woolly hair; his muzzle is long and pointed, and his ears erect, and slightly bent downwards at the tips; his tail is long and bushy; and the usual colour of his fur black and white, or varied with black and gray; the backs of his fore-legs have also long hairs. The peculiar and highly useful qualities of this dog seem to be rather intuitive than acquired; indeed, scarcely anything can exceed the quickness with which he is taught any lesson; and certainly no other dog has the same patient perseverance and courageous fidelity, or is at the same time possessed of greater discrimination. The labour of a shepherd, with the assistance of this faithful and intelligent animal, is comparatively an easy task; and it is hardly possible to fancy a more arduous employment than it would be, if divested of the services of the dog: for without him, how could he collect extensive flocks scattered over high and widely spread mountain-ranges? The shepherd's dog is possessed of great sagacity, gratitude, and self-denial, as is well known from innumerable anecdotes.

The *Cur*, or *Watch-dog*, differs from the shepherd's dog in being nearly smooth; he is stronger in his make, and has half-pricked ears, and his tail is rather short, and slightly feathered beneath. He is a trusty and useful servant to the farmer and grazier, and is chiefly employed in driving cattle; and being larger and stronger than the shepherd's dog, from which he is sprung, he is better qualified for the grazier and farmer. He bites with great keenness, and always makes his attack at the heels. His sagacity is very great, and he soon knows his master's fields, and watches with great assiduity the cattle which are in them. A cross between this and the true shepherd's dog has been found to be extremely useful on the sheep-runs of Australia.

The *German Dog* is a small-sized animal, with bushy turned-up tail, shaggy neck, small muzzle, and is generally of a cream-colour, but also sometimes black. His manner is brisk, and his character that of great fidelity. He is seen all over Central Germany, where he appears to be employed chiefly as a merry companion to man, and also for watching. A few specimens are beginning to be seen in England.

SECTION 5.—Water-dogs, which delight in swimming, having their feet in general semi-webbed.

The *Pomeranian*, or *Wolf-dog*, has the hair on the head, feet, and ears short; but it is long and silky on the body and tail, which last is curled up in a spiral form. His colour is white, black, gray, or sometimes yellowish; his head is long, and his muzzle pointed; his ears are short and pricked. He is possessed of intelligence nearly equal to that of the shepherd's dog, but is much less to be trusted.

The *Siberian Dog* has much the appearance of the Pomeranian dog, and is very nearly allied to him, except that he is covered with long hair, even on the head and paws. In their native country, four of these dogs are attached by pairs to a sledge, and in front of them is placed a leader, on the proper training of which much of the useful services of the others depends. These sledges are just large enough to contain one person, who directs the team with his voice, and in which he is partially assisted by a stick. The reins are fastened to the dogs' necks by a collar. Thus yoked, they have been known to drag a sledge from seventy to eighty miles in a day; and so powerful is their scent, that they contrive to keep on the beaten track by that means alone, even though it be obliterated by fallen snow.

The *Greenland Dog* is of a large size, strong in the bone, and its fur consists of long, thick-set, wool-like hair; his muzzle is sharp, and his ears short and pricked; his tail is thick, bushy, and spirally twisted. He is closely allied to the preceding variety.

The *Iceland Dog* is shorter in the hair than the above variety; his ears are pricked, but slightly bent downwards on the tips. His general colour is white, with patches of black differently disposed.

The *Esquimaux Dog.*—This highly useful variety is described by M. Desmarest as having the head shaped like that of the wolf-dog; the tail is spreading and curved, and the ears erect. The hair is thinly scattered, and consists of two sorts, the one silky, the other thick and fine, and somewhat curled, and so detached from the other that it may be pulled off in flakes from the animal. The dogs of the Esquimaux are very good-tempered and intelligent; active, swift, and enduring.

The *Hare-Indian Dog* has a narrow, elongated, and pointed muzzle; his ears are broad at the base, and pointed towards the tips, and perfectly erect; his legs are long and slender, and his tail thick, bushy, and curved slightly upwards, but by no means so decidedly curved as that of the Esquimaux dog. His body is covered with long straight hairs, the ground colour of which is white, marked with large irregular patches of grayish-black, intermingled with various shades of brown. Dr Richardson says it has neither courage nor strength for pulling down any of the larger animals. The feet of this variety are unusually large, spread, and thickly clothed with fur, in consequence of which they can run upon the snow with rapidity and ease without sinking.

The *Newfoundland Dog.*—This beautiful and intelligent dog is remarkable for the symmetry of his form and the acuteness of his understanding. He measures, from the tip of the nose to the point of the tail, six feet and a half, the length of the tail itself being two feet; from the one fore-foot to the other, over the shoulders, five feet eight inches; the girth behind the shoulders, three feet four inches; the length of his head is fourteen inches. He has webbed feet, in consequence of which he is a dexterous swimmer. His hair is long, flowing, and slightly curled, and his tail very bushy, particularly in the lower side, and he carries it in a very graceful manner. The docility of the Newfoundland dog is very great; there are innumerable most striking anecdotes of his sagacity and benevolence of disposition, particularly with reference to his saving persons from drowning. During the gale on Thursday, June 11, 1829, a vessel

was driven on the beach at Lydd; no boats could get off to the assistance of the crew, who were, however, all saved and brought ashore through the activity of a fine Newfoundland dog. The surf was rolling furiously, and eight poor fellows were crying for aid, which the spectators could not afford them, when one man directed the attention of his dog to the vessel, and the intelligent animal at once swam towards it, and the crew joyfully made fast a rope to a piece of wood, which the dog seized and swam with to his master on shore; a line of communication was thus formed, and the eight mariners rescued from a watery grave. Intelligent and sagacious as the Newfoundland dog undoubtedly is, there are certain occasions on which he is not to be trusted; and if sharply reproved or punished, is apt to resist the lash even of his master.

The *Russian Dog* is somewhat larger and stronger than the Newfoundland dog; he is a cross between that variety and the Siberian dog, and has now become a distinct race. His head is large, with his ears pendulous and rather full-sized; his tail is curled over his back; his hair is very long and shaggy, consisting of black and white patches.

The *Great Rough Water-dog* is web-footed, swims with great ease, and dives with much courage and dexterity; his hair is long and curly, and is of various colours; his legs and feet are also thickly covered with bushy hair.

The *Large Water-spaniel* is about the size of the English setter, but of a stronger make. His face is smooth, as also the front of his legs; while the rest of his body is covered with small crisped curls, usually of a dark liver-brown colour. This dog is very valuable in the sport of shooting wild-fowl.

The *Small Water-spaniel*, or *Poodle*, is a breed between the large water-dog and the springer; he is thickly covered with fine hair, all of which is in distinct small curls, more like an effort of art than of nature. It is one of the most active of dogs. Its general colour is white, and sometimes it has various black patches. It dives with much dexterity, and will leap from a very great height into the water; one has been known to leap over Old Tyne Bridge at Newcastle—a height of nearly fifty feet.

The *Shock Dog* is the smallest of the water-dog varieties, and is probably bred between the smaller spaniel or King Charles's dog and the poodle. Its hair is extremely long and flowing; so much so, that its ears and eyes are nearly concealed from view. It is kept only as a lapdog.

SECTION 6.—Fowlers, or dogs whose inclination is to chase and point birds, and hunt singly by the scent.

The *Springer* is shaped much like the English setter, but shorter in the body and legs in proportion to his size, being about two-fifths less than that dog; the hair is long and shaggy, and the ears very long and pendulous, and covered with long waved hairs. He is usually of a white colour, with patches of liver-colour or chestnut. He is, however, sometimes black, and at other times entirely of a liver-coloured brown.

The *Cocker* is about a third less than the springer, and like it in all respects. It is used as well as that variety for raising wood-cocks and snipes, in which exercise they are both very expert and hardy.

The *King Charles's Spaniel* is still less than the cocker, and distinguished by the very great length of his ears. Its hair is silky; and this, with its gentleness and small size, has rendered it a favourite pet of ladies of fashion. It was once fashionable for ladies to carry these little creatures in their arms while walking in the streets. They are sold at a high price.

The *Comforter* is another diminutive variety of this race, chiefly used as a lapdog. It is supposed to be a cross between the Maltese and King Charles's dog.

The *Maltese* and *Lion Dogs* are descendants from nearly the same stock. They are also favourites with the ladies; and are rare, but useless.

The *Alpine Spaniel*, or *Great St Bernard Dog*, exceeds other varieties of the spaniel for size and beauty. Its usual height is two feet at the shoulders; and the length from the nose to the tip of the tail is six feet. Two of these dogs are sent out from the monastery of the Great St Bernard, situated among the Alps of Switzerland, to scour the mountains during snow-storms, in search of lost or wearied travellers—the one with a warm cloak fastened to his back, and the other with a basket tied round his neck, containing a bottle with some cordial, and bread. In this employment they manifest great judgment, and seem to understand perfectly the import of their mission. They are frequently of the greatest use in meeting the travellers, who in those stormy and dangerous regions often fall victims to the inclemency of the weather. It is said that if they meet with a traveller who has sunk under the fatigue and inclemency of the blast, they will lie close to him, until by their warmth they restore heat and energy to the animation which is nearly suspended, and thus frequently will save the life of the sufferer. Should they discover a traveller to have fallen into some deep pit or fissure, whence he is unable to ascend, and if they are unable to render him any assistance, they will return to the convent and give the alarm to the monks, and then conduct them to the place where the unfortunate traveller is immured.

The *Old English Setter* is supposed to have been produced between the large water-spaniel and the Spanish pointer. The hair curled much more than in the present breed of setters, and they were very steady in the field, but not so rapid in their movements.

The *English Setter* is a mixed breed between the water-spaniel, Spanish pointer, and the springer, which has attained a very high degree of perfection as a sporting-dog. He is one of the most beautiful, lively, active, and hardy of dogs.

The *Spanish Pointer* is the stock from which the English pointer has sprung. He is one of the most stanch of all dogs used in the sports of the field, although he is considered too heavy for the present improved mode of sporting, and has now nearly become extinct in Great Britain.

The *English Pointer* was obtained by a cross of the Spanish pointer and foxhound, and is unrivalled for the

Newfoundland—Scotch Terrier—English Pointer—Cocker.

rapidity of his movements in the field, and the beauty and symmetry of his form. Since his first production, he has been improved by being recrossed with the harrier. He is subject to considerable variety in point of size as well as of colour. When well trained, and of a pure breed, he is exceedingly stanch—instances having been known where he has remained above an hour in the act of pointing.

The *Small Pointer* is a diminutive breed, being only

about two feet from the point of the nose to the tip of the tail, and scarcely a foot in height, and is a complete and beautiful miniature of the large pointer. They have proved themselves excellent sporting-dogs, but their small size renders them unfit for use in rough land.

The *Russian Pointer* is much like the Spanish pointer in shape, but his hair is long and wiry. He is valuable if well trained; but is rather obstinate and unyielding in temper.

The *Dalmatian* is a handsome animal, beautifully spotted black on a white skin. In his native country he is employed as a pointer; but imported into England, he has there lost all qualities for sporting, and is kept merely as an attendant on carriages—hence the common term 'coach-dog.' While most other dogs attach themselves to man, this one seems to care for nothing but horses. He lives by choice in the stable, and is happiest when running at the heels of the horses; even his own species he abandons in following this prevailing taste. He barks little, and is docile.

SECTION 7.—Hounds which hunt in packs by the scent.

The *English Terrier* is too well known to require any description. He is possessed of great courage, and is famous for killing all kinds of vermin, and at one time formed a useful attendant upon a pack of foxhounds, for getting into the earth when the fox had taken to his hole, and driving him out. His hair is smooth; his general colour is black, with tanned cheeks, and the insides of his legs are of the same colour. They are now to be met with of a brown, and even white colour; but these have unquestionably an admixture of some other breed in them.

The *Scotch Terrier* has short wiry hair, very rough, and is much shorter in the legs than the English terrier. His usual colour is sandy, but he is to be found black, and also gray. He bites with great keenness, and is a bold and determined dog. He will attack dogs of any size; and when he fixes on an animal, he maintains his hold with great pertinacity. He was at one time much used as an attendant upon packs of foxhounds, and forms an excellent killer of vermin. The *Skye terriers*, or terriers of the Western Isles, are longer in the body, lower in the legs, and decidedly rougher and shaggier than those of the Lowlands; indeed, they form altogether a distinct variety.

The *Talbot* is one of the primitive breeds of British dogs, and is the same which was used by the ancient Britons in the chase of the deer and other wild animals. It is now, we believe, extinct, or at least not in common use. He had a broad mouth, very deep chops, large pendulous ears, was fine-coated, and usually of a white colour. He was formerly known as 'St Hubert's breed,' and was distinct from the blood-hound, though by some confounded with that dog.

The *Blood-hound* is a powerful and sagacious animal, generally of a dark colour, with brown markings, and is endowed with a keen scent. On being led upon the footsteps of any animal or man, he will follow them up with unerring precision. This has led to the breed being employed for tracking criminals, or the unhappy victims of oppression. By the Spaniards, a breed was taken to Cuba to track the natives, and this race of animals still exists in that island. A correspondent in a newspaper thus speaks of them:—'At a period not very remote, the unfortunate negroes in the Spanish settlements were frequently torn to pieces by the Cuba blood-hounds. In fact, under the title of Chasseurs, the Spaniards maintained regular regiments of these dogs and their attendants. In pursuing or hunting the runaway negroes, the chasseur is generally accompanied by two dogs, and armed with a *couteau de chasse*, or straight sword; and we are informed that these blood-hounds, when well and properly trained, on coming up with the object of pursuit, will not kill him unless resistance is offered, but bark at and terrify him till he stops, when they crouch near him, and, by barking, give their keepers notice, who approach accordingly, and secure their prisoner.

'Dallas, in his account of the Maroon War in Jamaica, mentions an importation of these Cuba blood-hounds, in order to assist the regular troops in reducing the refractory Maroons. It may seem strange that dogs were called to the assistance of well-disciplined soldiers; but in order to elucidate the subject, it must be observed that the armed Maroons, under the conduct of various cunning leaders, particularly of Cudjoe, Smith, and Johnson, aware of their own inferiority in point of that organisation which constitutes the strength and essence of a regular army, cautiously avoided meeting their opponents on the plain; on the contrary, they retired to the impenetrable fastnesses of the woods and mountains, and by means of ambuscades, contrived so to harass the troops, that the governor of Jamaica ultimately procured a company of these dogs and their attendants from Cuba, which arrived at Jamaica under the command of Don Manuel de Sejas; and a tolerable idea of these dogs may be formed from a review which took place immediately after their arrival. General Walpole, who conducted the war against the Maroons, being anxious to review these chasseurs, left head-quarters the morning after they landed, accompanied by Colonel Skinner, and arrived in a postchaise at Seven Rivers. Notice of the general's approach having been given, the chasseurs were taken to a distance from the house, in order to advance when he arrived. The Spaniards were drawn up in a line at the end of a gentle declivity, and consisted of upwards of forty men, with their dogs in front unmuzzled, and held by cotton ropes, as it was intended to ascertain what effect would be produced on the dogs if actually engaged under a fire of the Maroons. The Spaniards, upon the word being given, fired their fusees, when the dogs pressed forward with almost ungovernable fury, amidst the shouts of their keepers, whom they dragged along with irresistible impetuosity. Some of these ferocious animals, maddened by the shout of attack, and held in check by the ropes, actually seized upon the gun-stocks in the hands of the chasseurs, and tore pieces out of them. The unfortunate Maroons, who had successfully opposed all the efforts of regular troops, were panic-struck on the arrival of the blood-hounds, and surrendered without once daring to come in contact with animals which at best could oppose but a feeble resistance to firearms.'

The *Staghound* is the largest of all the British dogs of the chase; he has a noble and dignified aspect, and possesses great sagacity and endurance in the chase: this dog is also supposed to be a direct descendant of one of our original British dogs.

The *Foxhound* has a much larger muzzle than the staghound, and his head is small in proportion to the size of his body; his ears are very long and pendulous, although less so than those of the staghound and blood-hound. Though a determined enemy of the fox, this active hound is by no means destitute of warm affections. A foxhound bitch, belonging to the Kivington Hunt, near Bolton, on the 8th of November 1792, during the chase, pupped four whelps, which she carefully covered in a rush aisle, and immediately afterwards joined the pack. In a short time after, she pupped another, which she carried in her mouth during the remainder of a hard chase of several miles, to the great astonishment of a number of spectators, after which she returned to the place where she had originally dropped the four.

The *Harrier* is used in hare-hunting, and was originally obtained by a double cross between the small beagle and southern hound. He is very eager in the pursuit of the hare. There are few instances of any of the deer tribe being hunted with success by dogs of so small a description as harriers.

The *Beagle* is the smallest of the dogs of the chase. He is possessed of a very acute sense of smelling, and

pursues the hare with unwearied steadiness; and what he wants in speed and strength, he makes up by his perseverance.

The *Otter-hound* is a cross between the large southern hound and the large rough terrier. He has a large head, with pendulous ears, and his whole fur is of a wiry texture, and rather long; his colour is either sandy or black. Otter-hunting was a favourite sport in ancient times, but is now seldom pursued.

The *Bull-terrier* is a cross between the bull-dog and the terrier, as its name implies, and has now assumed the character of a distinct breed. It is much used by gentlemen of the fancy as a fighting dog; it forms likewise a first-rate animal for the chain.

SECTION 8.—Mongrel hounds, which hunt singly either by the scent or by the eye.

The *Lurcher* is a cross between the greyhound and harrier, and recrossed with the terrier. His limbs are strong; his head less sharp than that of a greyhound; his ears are short, erect, and half pricked; and his hair coarse and wiry. He is much used by poachers, and is famous for killing rabbits, as he has a fine scent, and runs his game without giving tongue.

The *Leymmer* and the *Tumbler* are imperfectly known dogs, which are now nearly if not entirely extinct. They hunted both by the scent and eye.

The *Turnspit* is a small dog with a long body and short crooked limbs, and was much used in turning the spit before the invention of jacks. Breeds between this now useless variety of dogs and mongrel terriers and hounds, appear to form the nondescript and ugly races of animals which haunt the streets of our large towns, but whose numbers are now diminishing by the proper interference of the police.

III.—With Short Heads.

SECTION 9.—Watch-dogs, which have no propensity for hunting.

The *Mastiff* has a large flat head, and a short and blunted muzzle; his lips are full, and hanging considerably over the lower jaw; his ears, although rather small, are pendulous. He has a sullen and grave aspect, and is excellent as a watch-dog; his voice is loud and deep-toned. He is a dog of large size, and is supposed to have been produced betwixt the Irish greyhound and English bull-dog. Like the dog next mentioned, he is ferocious in disposition, and of little use when out of the chain.

The *Bull-dog* is remarkable for the depth of his chest and the strength of the whole muscles of his body. His head is large, flattened above, and his muzzle much blunted, with the under jaw projecting considerably beyond the upper one; his eyes are set far apart, and project somewhat from his head; his power of smelling is less acute than any other of the canine race, on which account he is a dangerous dog, for he has frequently been known to lay hold of his master without discriminating the difference between him and a stranger. He is the boldest and most obstinate of all dogs, and has been known to hold his adversary so determinedly that his legs have been cut off without making him desist.

Many instances have been recorded of the invincible courage of the English bull-dog, but we scarcely recollect one in which so much unconquerable spirit and tenacity of life have ever been displayed as on the following occasion:—Some years ago, a large dog of this species, from some cause that was not observed, suddenly flew at a fine cart-horse that was standing at the end of the Salthouse Dock, Liverpool, and fixing his lacerating teeth in his shoulder, defied every effort to get him off. At first he was beaten with cart-whips and sticks, with much fury; but this being unavailing, a carpenter with an adze in his hand came up and beat him with the blunt iron head of the instrument, but the dog never moved a tooth. A man then took out a large pointed clasp-knife, with which he stabbed him repeatedly in the back, loins, and ribs, but with no better success. At length one of the spectators, who appeared to have more strength of sinew and arm than the rest, squeezed the ferocious beast so tightly about the throat, that at length he turned up the white of his eyes and relaxed his jaws. The man threw him off to a distance, but the dog immediately went round the crowd, got behind the horse, and again seized him by the under part of the thigh. As no terms could now be kept with this untamable brute, he was again loosened and thrown into the dock to drown. He instantly, however, rose to the surface, when a sailor struck him a supposed deadly blow on the head with a handspike, which again sent him to the bottom. He arose once more, and was again sent down in the same manner, and this process was repeated five or six times. At length one of the bystanders, who either possessed or assumed some right of property in the dog, overcome by his amazing tenacity of life, and weary of persecution, got him out, and walked off with this prodigy of English courage, to all appearance very little the worse for the horrible punishment he had undergone. Since the very proper disuse of bull-baiting, this ferocious variety of the dog has fortunately diminished in number.

The *Pug-dog* is descended from the bull-dog, by a cross with the small Danish dog, and resembles the former so much in appearance that he may be considered as a miniature of that variety. He is a useless dog, and with generally a bad temper, has no good quality to recommend him.

GENERAL MANAGEMENT.

As formerly mentioned, dogs are very susceptible of education, and will fall into such habits as are impressed upon them by a course of training. Whatever be the peculiar variety kept in or about a dwelling-house, it is important that he be at least taught good manners; as, for example, to be silent and lie down when bidden, to refrain from leaping on the knees of persons visiting the family, and not to sit staring at meals, watching every bit that is put in the mouth. To make a dog behave properly in these and other points, he must be carefully taught when young, and for this purpose his master requires to employ a judicious mixture of severity and gentleness. He must be made fully aware that he must do as he is bid; that if he do not, he will be punished, but that if he obey, he will be rewarded. As all dogs are very tractable in such matters, they will soon learn to comprehend the meaning of a look, a sign, or a word, and will act accordingly. As very few persons take the trouble to teach domestic dogs either one line of conduct or another, we see on all occasions instances of the natural consequences of such neglect.

Breeding.

The best dogs are produced from parents not less than two years old, to which period a valuable bitch should be reserved. All who are interested in preserving the breed of their dogs should on no account suffer a cross. In every instance, let the male and female be of the true breed designed, not mixed or deteriorated. If a slight alteration of character be desirable, a cross of the English bull-dog will be found useful by giving determination. Breed always from the healthiest and best-shaped animals. Mongrel breeds are good for nothing.

Breeders of sporting-dogs require to pay marked attention to these principles. According to the author of the *Oakleigh Shooting-guide*, the theory respecting pointers is, 'that the further any dog is removed from the original Spanish pointer, the worse the dog is; and, consequently, that all attempts to cross the pointer with any other blood must necessarily deteriorate the breed. The greyhound is seldom or never crossed to give him additional fleetness, nor the hound to improve his nose;

why, then, should the pointer be crossed with dogs which, in so far as the sports of the field are concerned, scarcely inherit one quality in common with him? Attempts, however, are constantly made to improve the pointer by a cross with the blood-hound, foxhound, Newfoundland dog, or mastiff, sometimes with a view of improving his appearance, and bringing him to some fancied standard of perfection, but in reality inducing a deformity. The best pointer is the offspring of a pointer-bitch by a pointer-dog; such a one is nearly broken or trained by nature. The Spanish [or true] pointer seldom requires the whip; the hound-pointer has never enough of it.' The same writer continues—'Dogs should be constantly shot over during the season by a successful shot, and exercised during the shooting recess by some person who understands well the management of them, otherwise they will fall off in value—the half-bred ones will become unmanageable, and even the thorough-bred ones will acquire disorderly habits.'

It appears that the females are liable to receive mental impressions of the appearance of the males with which they have been in company, and that these remembrances will affect their progeny even for years afterwards. We beg to refer to Blaine's *Encyclopædia of Rural Sports*, p. 412, for some interesting information on this subject.

Whelps, at a month old, are generally deprived of their dew-claws. With some varieties it is also the custom to shorten the ears and tail, with a view of improving their appearance; but it is questionable if any breed can be improved in aspect by such treatment, and certainly no pure and well-formed variety can benefit by such mutilations. There is a prejudice of very old standing, that dogs have a worm beneath their tongue, and that the removal of this, called *worming*, deprives the animal of the power of biting should it become rabid. No worm exists; and it is doubtful if the process is of any use. That which is called a worm is merely a minute ligament or fibrous cord in the bridle beneath the tongue; and when the bridle is cut, the ligament may be drawn forward and separated at both extremities; the contraction of the ligament, on extraction, resembles the movement of a worm, and hence the origin of the term.

Feeding.

Some of the most troublesome traits in the dog's behaviour arise from mismanagement in feeding. If a dog be half-hungered, he cannot be blamed for watching the breakfast or dinner table. We advise all who indulge themselves with keeping dogs, not to leave their feeding to the chance scraps of either the kitchen or the parlour. Give the dog his own regular meals, and with food suitable to his wants or the duty he has to perform. The food should be chiefly flesh of some kind, boiled and cold; if given raw, it has a tendency to foster ferocity of disposition, and will cause the animal to be offensive in smell. No pet-dog, especially, should ever be allowed to eat raw meat. Any common pieces of flesh or tripe will answer for dog's meat. Some persons give liver, which is decidedly bad; it relaxes the bowels, and is otherwise objectionable. Besides the piece of boiled meat considered necessary, give dogs a few bones from the dinner-table; they are fond of these, and they are useful in cleaning and preserving their teeth, and keeping their bowels in order. If the dogs will take it, they should also be given a little farinaceous food, as morsels of bread or a little oatmeal porridge with milk.

The nature of the dog leads him to feed well when food is offered to his appetite, and to feed seldom. Once a day, therefore, is, in ordinary circumstances, sufficiently frequent for his meals. Present him with his allowance in the morning or forenoon, and give him no more till next day. He, however, requires to drink frequently; and it is a leading rule in keeping a dog, to have at all times a pan of clean cold water ready for his use. Change the water daily, or oftener.

For the feeding of hounds, Daniel recommends that flesh meat should be alternated with a diet of oatmeal porridge made with broth in which meat has been boiled. Greens boiled in their meat is also proper. 'A horse killed and given to the hounds whilst warm, after a very hard day, is an excellent meal; but they should not hunt till the third day after it. The bones broken are good for poor hounds, as there is great proof in them. Sheep trotters are very sweet food; and bullock's paunches may also be of service in a scarcity of horse-flesh. Hounds should be sharp-set before hunting; they run the better for it.' The same excellent authority continues to observe, that hounds should be fed once when returned from the fatigues of the chase, and again some time afterwards. 'It is the best plan to feed twice the hounds that have been out. Some hounds will feed better the second time than the first; besides, turning them out from the lodging-house refreshes them; they stretch their limbs, and the litter being shaken up, and the kennel cleaned out, they settle themselves better on the benches afterwards. At all times, after being fed, the hounds should be turned into the grass-court to empty themselves; it will not a little contribute to the cleanliness and health of the kennel.'

Lodging—Kennel Treatment.

Dogs require to be lodged in a dry situation, at a moderate temperature. The practice of keeping dogs out all night during frosty weather, or of putting them into cold coach-houses, is most inhumane and disgraceful. Those kept for watching the outside of premises should be provided with a comfortable house of wood, bedded with clean straw, and sheltered from cutting winds. A dog kept in a dwelling-house should have an appointed place, as in a lobby, for sleeping; its berth should consist of a basket, open box, or small house, according to the taste of the animal. A spaniel will not go into a dog-house; a terrier prefers it. In any case, the berth should be laid with a mat or carpet, which must be frequently washed.

Damp is seriously injurious to dogs. It produces rheumatisms, which shew themselves by lameness in the shoulders, and other disorders detrimental to their usefulness. It is therefore of great importance to build kennels in airy situations, and to keep them dry and airy. The best kennels are paved with tiles or stone, but on the floors there are raised benches, littered with straw in winter, on which the dogs repose. The straw should be daily changed, nothing being of so much consequence as cleanliness, both for the sake of general health, and preserving the powers of scent of the animals. For this latter purpose some keepers of packs of hounds have a change of rooms, one being used while the others are becoming sweet after cleaning. On this subject Daniel observes: 'The excellent sense of smelling, so peculiar to the hound, is what our sport entirely depends on; care therefore must be taken to preserve it, and the utmost cleanliness is the surest method: to keep the kennel sweet cannot be too much recommended, and is on no account to be neglected. The exactness of the master in this particular will insure that of the feeder.

'Hounds that come home lame should not be taken out the next hunting-day, since they may appear sound without being so. At the beginning of a season, the eyes of hounds are frequently injured; such hounds should not be hunted; and if their eyes continue weak, should lose a little blood. Such as have sore feet should have them well washed out with brine or pot-liquor. Hounds unable to work should be permitted to run about the house; it will be of great use to them; and such as are ill or lame ought to be turned into a kennel by themselves; there it will be more easy to give that attention both to their medicine and food which is requisite.'

Hounds which are properly disciplined are obedient in a very extraordinary degree to the orders of the

huntsman. 'To see,' says the writer of the article Hunting, in the *Encyclopædia Britannica*, 'sixty couples of hounds, animals all hungry as tigers, standing aloof in their yard, and without even hearing, much less feeling, the whip, not daring to move until the order is given to them. And what is the order given? Why, at the words "Come over, bitches," or "Come over, dogs," every hound of each individual sex comes forward, as the sex it belongs to may be called for, leaving those of the other sex in their places. Then the act of drawing them to the feeding-troughs is an exceedingly interesting sight—often, with the door wide open, having nothing to do but to call each hound by his name, which of course he answers readily to. The expression of countenance, too, at this time is well worthy of notice; and that of earnest solicitation, of entreaty, we might almost say of importunity, cannot be more forcibly displayed than in the face of a hungry hound awaiting his turn to draw. He appears absolutely to watch the lips of the huntsman, anticipating his own name.'

Health—Disease.

All dogs whatsoever, but those designed for field-sports in particular, require to be kept in what is called 'condition;' that is, neither too fat nor too lean, but the body in that hardy and active state that will enable the animal to perform its duties. If loaded with flesh or fat, it will not possess wind, or a due power of quick breathing, for any length of time in the chase. Colonel Cook observes, on what constitutes a proper condition: 'The ribs should be visible, and the flank moderately hollow, but the loins must be well filled up in a dog in perfect condition. When dogs exhibit general fulness and too much flesh, commence by physic and a regular course of exercise, which should be mild at first, but increased until it is severe. Avoid too great a privation of food, otherwise the conditioning process will be retarded.'

To keep a dog in a state of good health, he must not only be regularly fed and admitted freely to water, but be allowed plenty exercise daily in the open air, and kept in a cleanly condition. If his bowels appear relaxed, he is not in sound health; and as a preventive of this, let his food, as already said, be substantial, and consist partly of bones; let him also have access to grass; every proper kennel has a grass-yard to which the dogs can resort. In the pan of water used by house-dogs put a piece of brimstone; it slightly affects the water by lying in it, and helps to keep the animals cool.

All dogs are liable to be troubled with fleas, which they get from the ground; the skin also contracts dirt, and from that or other causes becomes offensive in smell. The remedy is cleanliness. Every lap or house dog should be washed at least once a week with soap and water. Some dogs have a great dislike to washing, but it must nevertheless be performed. After washing thoroughly, rub the animal dry with a hard cloth, and comb and brush it. If there be fleas, a small-toothed comb will remove them, and they should be killed as they appear. Wash and dry delicate dogs before the fire.

On the subject of physicking as a preventive of disease, or when there are symptoms of diseased skin, a little sulphur and antimony is recommended, mixed with the meat, or done up as a bolus or pill, and in this latter form pushed over the throat. 'Once a week or fortnight,' says Daniel, 'during the hunting-season, hounds should have one pound of sulphur given them in their meat; and when the season is over, half a pound of antimony should be added to the sulphur, and well mixed with the meat. This cools, and is doubtless of service to them.'

The *Mange* is a cutaneous disease in dogs, very closely resembling itch in the human species, but more inveterate, and is hereditary as well as contagious. Mr Blaine, in his *Encyclopædia of Rural Sports*, thus speaks of this nauseous complaint: 'Of all the causes which beget mange—and they are not few—the acrid effluvium from their own secretions is the most common; when it is generated by numbers, particularly when it is confined within a limited space, it is sure to appear. Close confinement of any dog will commonly produce it, and most certainly so if it be at the same time fed on salt provisions; thus there are few dogs on shipboard that do not contract it, except such as are allowed full liberty of the deck. Food too nutritive in quality, and too considerable in quantity, is productive of mange; and, on the contrary, food in a great measure withheld, or being very poor in quality, is equally a parent of the disease.' The same authority gives several recipes of medicine to be employed; the leading are—powdered sulphur, four ounces; muriate of ammonia (sal-ammoniac) powdered, half an ounce; aloes powdered, one drachm; Venice turpentine, half an ounce; lard or other fatty matter, six ounces: the whole to be mixed and administered in boluses. In all bad cases, however, we should recommend no one to attempt doctoring his dog, but to apply to a regular practitioner.

Distemper.—This disease is most common among dogs which are much kept in the house and subjected to artificial treatment. The disorder is epidemical, affects the constitution, and is very difficult of removal. It is now considered to be typhus fever, and should be treated on the same principles as that disease in the human subject. W. H. Scott, in his work on *British Field-sports*, thus describes the symptoms of distemper in a young dog: 'Sudden loss of usual spirit, activity, and appetite; drowsiness, dulness of the eyes, and lying at length with the nose to the ground; coldness of the extremities, ears, and legs, and heat of the head and body; sudden emaciation, and excessive weakness, particularly in the hinder quarters, which begin to sink and drag after the animal; an apparent tendency to evacuate from the bowels, a little at a time; sometimes vomiting; eyes and nose often, but not always, affected with a catarrhal discharge. In an advanced stage of the distemper, such symptoms will occur as spasmodic and convulsive twitchings, the nervous and muscular systems being materially affected; giddiness and turning round, foaming at the mouth, and fits. The disease is then often taken for incipient madness, into which it might not improbably degenerate.' The same authority adds: 'I have found daily mild doses of from two to three grains of calomel alone, lapped by the animal in milk, continued for four or five days, with intermissions when necessary, fully sufficient to carry it safely through the disease, even when the fever has been very high. James's powder has, however, always proved the most certain remedy.' A tea-spoonful of sulphur given weekly in milk, from the age of three to twelve months, renders the disease very mild, and has been found of the greatest service by those who have tried this simple plan. To aid recovery, nourishing diet should be given. In cases of severity, consult the veterinary surgeon.

Rabies, or *canine madness*, is the most fatal malady to which dogs are subject, and for which, so far as we have heard, there is no certain cure. Blaine considers that rabies is never produced spontaneously in dogs or any other animals, but is invariably the effect of inoculation by a bite from a dog already mad. But as the disease must have commenced spontaneously in some dog at first, we do not understand why it may not do so again; in short, the doctrine, in the exclusive form in which it is put, seems untenable. Rabies is little known in hot or cold countries; it is common chiefly in temperate regions, but shews itself principally in summer, when it may be supposed to be excited by a feverish condition of body.

The leading symptom of the rabid state is an apparent discomfort and unsettledness of purpose, with a desire to gnaw and eat anything within reach, as straw, wood, coal, or any other rubbish; as the disease advances, the

animal snaps and bites at everybody, or any animal near it. This is, however, no effect of bad temper; the dog has no wish to go out of his way to bite; he is under the influence of a derangement which makes him catch only at what is near. Like the unnatural appetite he possesses, the snapping propensity may also partly arise from the irritated state of the stomach and intestines, both of which are greatly inflamed. The throat is likewise livid; and by a constriction of parts, soon prevents the animal from swallowing. *Hydrophobia* is the name of a human disease produced by the bite of a dog affected with rabies. In it the dread of water is the most marked symptom, whilst in rabies there is a decided desire for water. In the later stages of the disease paralysis ensues, and from the fourth to the seventh day the dog expires. It is humanity to shoot the animal before this final catastrophe.

With respect to the production of rabies in the human species, there have been some very grave doubts. An idea has been started, and supported with considerable plausibility of argument by certain medical practitioners, that hydrophobia in the human being is merely a nervous affection, very much, if not almost altogether, arising from the influence of the imagination; the person bit fancies he is going mad, and mad he becomes. It is very desirable that the medical world should investigate and arrive at some determinate conclusion respecting this remarkable doctrine; meanwhile, till the matter is settled one way or other, we must speak of rabies in the human subject as a real disease, against which every reasonable precaution should be adopted. On being bit, it is always safe to wash the wound immediately, and have the parts burnt with a hot iron, or cut out. In every case let a skilled surgeon be immediately consulted—one who will not hesitate to act with promptitude and decision.

Many cures have been mentioned for the bite of a mad dog. We shall notice a few. The following, according to Blaine, is the famous Herefordshire cure, commonly called *Webb's drink*:—'Take the fresh leaves of the box-tree, two ounces; of the fresh leaves of rue, two ounces; of sage, half an ounce; chop these finely, and after boiling them in a pint of water to half a pint, strain and press out the liquor; beat them in a mortar, or otherwise bruise them thoroughly, and boil them again in a pint of new milk, until the quantity decreases to half a pint, which press out as before. After this, mix both the boiled liquors, which will make three doses for a human subject. Double this quantity will form three doses for a horse or cow; two-thirds of it is sufficient for a large dog, calf, sheep, or hog; half the quantity is required for a middle-sized dog; and one-third for a smaller one. These three doses are said to be sufficient; and one of them is directed to be given every morning fasting.' Blaine has not much confidence in this remedy, but allows it is worth trying. Mr Murray, known as a lecturer on chemistry, mentions, in a letter to a newspaper, the following remedy:—'Let a mixture of two parts of nitric and one part of muriatic acid, both by measure (evolving chlorine in a concentrated form) be applied to the wound as soon as possible, and more than once.' He adds that he has found this a preventive. M. Buisson, a Parisian physician, declares that madness from the bite of a rabid dog may be thoroughly cured by fumigating the patient in a hot vapour-bath, and afterwards keeping up the copious perspiration in bed; this he recommends to be done for several successive nights.*

FIELD-SPORTS.

Conducted on principles of moderation, humanity, and fair-play, the sports of the field may be said to be those exhilarating and healthful pursuits by which the tribes of wild animals are made subservient to man's use, or removed from a sphere in which they are inconvenient and unsuitable. In taking amusement from such sports, it is the glory of the true English gentleman to avoid every proceeding which can give unnecessary pain to the animals over which he claims dominion, and to discountenance by every means in his power such odious abuses of sport as baiting, worrying at the stake, or any other method of protracting the death of the creatures who have the misfortune to be objects of the chase. Our limited space will permit us to notice only the leading field-sports of Britain in past and present times.

FALCONRY.

Falconry was the favourite field-sport of the middle ages, as shooting with the gun is the predominant one of the present day. It appears, in this country, to have declined and gone out of use in the seventeenth century, in consequence of the gun having then become, by the addition of the lock and flint, a much more ready means of bringing down game than the use of hawks had ever been. Falconry, while it existed, was the peculiar sport of kings, and princes, and nobles, many of whom were painted in life with their hawks seated on the wrist, and were sculptured on their tombs after death with the same creature placed at their feet; thus marking the special regard in which they held the animal which was the means of giving them so much amusement.

The sport, we need scarcely remark, was founded on the natural instinct of the rapacious order of the feathered creation, as the chase may be said to be founded on the instinct of the dog to pursue the hare, fox, and other animals. The rapacious order of birds—of which the eagle, falcon, and owl are the three principal types—are formed in such a way as evidently fits them for pursuing, seizing, and destroying the smaller birds; a part in creation which at first sight appears to involve much cruelty, but which has been clearly shewn to be intended to save rather than to produce pain, and to be indispensable to a system of things in which one leading feature is, that there shall always be as many living creatures as can possibly be supported. The falcon family were alone employed for purposes of sport, as alone possessing the required docility; and of this family two or three species were more frequently used than any other. Of those possessing long wings, the falcon proper and the gyrfalcon; and of the short-winged, the goshawk and sparrow-hawk, seem to have been the favourite kinds. Species called the hobby, the kestrel, the merlin, and buzzard, were the next in request. The female, which is in all the varieties of this tribe considerably larger than the male, was alone employed in sport, and the common names of all the species apply to that sex, the male having usually some distinctive appellation: thus the male of the gyrfalcon was called the *jerkin;* of the falcon proper, the *tierce gentle;* of the goshawk, the *tiercel;* and of the sparrow-hawk, the *musket.*

These birds naturally choose retired habitations. The falcon, in particular, builds her nest amongst cliffs in wild and unpeopled regions. In order to fit birds for the sport of falconry, it was necessary to take them from the nest at a very early stage of their existence (then technically called *eyasses*), or to insnare them in their more mature age, and then train them for the purpose. A falcon in its natural state was said to be a *haggard.* The first step in training the falcon was to *man* it, or accustom it to the presence of human beings. Feeding was the grand source of the power which its keeper acquired over it. When it did as required, it was fed, and thus taught to know that it had done right, and not otherwise. If extremely refractory, a stream of cold water was directed at its head, as an admonition that

* See an account of Buisson's proceedings in *Chambers's Edinburgh Journal*, No. 257, old series.

nothing was to be gained by such conduct. From the very first, the animal was accoutred with certain paraphernalia, the *names* of which at least must be familiar to most readers. First, its head was covered by a leathern *hood*, fitting close all round, so as to shut up its eyes, and calculated, by a slit behind, to be readily slipped on and off. On the top of the hood there was a tuft of feathers, which usually has a graceful effect in the old pictures representing ladies or gentlemen travelling with their hawks upon the wrist. Leathern straps, called *jesses*, a few inches in length, were fitted to the legs of the bird by a button slipping through a slit or loop. Close beside the end attached to each leg was a small spherical *bell*, like that of a child's rattle, and composed of silver, for clearness of sound, the one being in some nice instances made a semitone higher than the other. The other ends of the jesses were furnished each with a ring, which could be readily fitted upon the swivel designed to connect them both with the *leash*, a long slender strap, sometimes prolonged by a *creance*, or common cord, and designed as a tether by which to restrain the animal, at the same time that it should be allowed considerable room for free motion. Two great objects in training were to teach the bird to fly at its proper game, and to habituate it to come back to the hand of its master, after on any occasion having been let free in pursuit of its prey. For the first of these ends, in the case of long-winged birds, an implement termed the *lure* was used. It consisted either of a stick or of a cord, on the end of which were fixed pieces of flesh, with a bunch of the feathers of the prey which it was designed that the bird should fly at, or perhaps an actual resemblance of the prey in its entire form. The falcon being set loose by one man, another stood at a distance waving the lure around his head, thus tempting the animal to advance and strike at it. A whistle was the implement used to *reclaim* or bring back the hawk. When a hawk was to be kept on the hand, strong gloves were worn for protection from its talons. It may here be remarked, that the training of falcons was altogether a most laborious business, and that trained birds were accordingly to be purchased only at a high price. At the beginning of the seventeenth century, a trained goshawk and tiercel brought 100 marks, and it was considered a favour to part with them. The extreme labour attending the training of the animals must have been sufficient in early times to confine the sport to persons of birth and fortune, if there were no other cause; and it must also have conduced to the rapid decline and extinction of the sport, after a ready means of killing wild-fowl by the gun became attainable.

The sport, after being long given up, was revived in England some years ago by the Duke of St Albans, Colonel Thornton, and a few other gentlemen, chiefly through the influence of a taste for whatever is elegant and romantic in the usages of our forefathers. It is said to be a gallant and goodly sight, when a cavalcade of well-mounted English ladies and gentlemen rides forth on a clear sunshiny day to pursue this sport, attended by their falconers, each with his hawk on his wrist. In the present day, as of yore, various kinds of feathered game are flown at. Heron-hawking is, we believe, in greatest esteem. The heron, as must be generally known, is a large bird in appearance, with a long neck, long legs, and a long sharp bill, being designed to haunt marshes and pools, and feed upon whatever fish it can find therein. It is, however, a light unsubstantial bird, with nothing to protect it from enemies but its sharp bill. Herons are gregarious, and the places where they live are called heronries. These explanations will introduce the following account of heron-hawking, from Blaine's *Encyclopædia of Rural Sports*:—

'The daily visitations of the heron to its feeding-places are watched by the falconers, who station themselves to the leeward or down wind of the heronry, so that the heron, on its return, must fly against the breeze, which gives a great advantage to its enemy. As soon as one is discovered on the return, a cast of falcons is let loose, who, catching sight of the quarry, rise in pursuit. The heron, instinctively aware that its life is at stake, prepares for the fray by disgorging the contents of its stomach to lighten the weight of the body. The coursing falcons ascend the airy vault in spiral gyrations, by which the atmospheric resistance to their flight is lessened. These circlings, it has been observed, have frequently the curious effect of presenting the three birds as flying in different directions; whereas the real intentions of the two hawks are steadily directed to one point, which is that of contact with the heron, whose entire efforts are as steadily engaged in avoiding it. To effect this, the affrighted heron strenuously endeavours to rise above the hawks, who, however, by the superior power of wing, commonly succeed in getting the upper station, from which one presently makes its stoop; and happy it is for the poor heron if he can evade the blow, which he occasionally does, either by shifting his station, or by receiving the falcon on his sharp bill, which instantly transfixes it. This danger is, however, denied on authority, but we feel assured that it does occur. The second hawk, if the first fails, stoops in his turn; but the meditated blow of this also is frequently evaded like the former. The trio then still rising higher and higher, the sight becomes interesting in the extreme, and the spectators are scarcely less agitated than the feathered warriors above. At length another stoop takes place, and the fatal seizure is made by one hawk, while the other *binds* to his fellow, and all three quickly descend together, but not with a dangerous rapidity, as their powers of inflation and the action of their wings break the fall. It is now that the mounted horsemen make the best of their way to the assistance of their falcons, and their first efforts must be directed to secure the head of the heron, that the sharp beak may not take effect on one or both of them.'

Pheasants are objects of this sport, but not to a great extent, on account of the inconvenience presented by the silvan ground in which the sport must be practised. Partridge-hawking is found to be a more convenient sport. To quote the same authority: 'The scene of practice is commonly on large fields or open tracts of country, where the horsemen and company generally can beat in line, and the attendant falconer or master, being well mounted, can ride forward, and be ready to receive the quarry. Either pointers or spaniels are necessary, or both. The partridge being flushed, the hawk will stoop with astonishing rapidity, and seize on it; at which time neither horses, dogs, nor company should press forward: on the contrary, they should permit the falconer only to advance, who, approaching the hawk with caution, must walk quietly round her, when, gently kneeling down with his arm extended, as though in the act of feeding the hawk, he should lay hold of the partridge, and at the same time place the hawk on his fist. This done, restore the hood, and reward the hawk with the head of the quarry; and if she be not intended to be flown again, let her be fed immediately.

'A somewhat different method of partridge-hawking is practised in the latter part of the season, when the country is very bare, and when the partridges are often very wild, and lie indifferently even to the dog. In such cases it is recommended that the company "draw up in line at fifty or sixty yards' distance from each other, and gallop across the plain with a hawk upon wing," the falconer being in the centre of the line, that he may regulate the pace by the situation of the hawk. Sir John Sebright informs us, that this method of partridge-hawking has afforded him more sport than any other, and that when the face of the country was so bare, and the birds so wild, as to make it impossible to approach them in the usual way.

'Brook-hawking, as it is often termed, was much in vogue formerly. The practice was not, however, confined to brooks, but extended to rivers, sea-shores, moors, and ponds. It engaged, according to Blome, "the ger-falcon, the haggard-falcon, the jerkin, and the tassel gentle." Water-fowl of every description were made prey of; but some particular objects, according with the training of the falcons, were particularly sought for. Dogs were employed to rouse the fowl, being led on by men who traversed the water's edge; while horsemen, with the hawks on their fists, were at hand to *cast off* one or more, according to the nature of the game. A heron or mallard would require two, while a widgeon or a teal (being small) would probably engage only one.'

DEER-HUNTING.

Deer-hunting was another principal amusement of past times, but has now been abandoned in the form in which it used to be conducted. The species of animals chiefly hunted in England was the fallow-deer, a beautiful creature with stately horns and antlers, and of great speed in running. Fallow-deer are now closed up in parks, at least in Britain. The stag, red deer, or hart, whose female is called the hind, differs in size and in horns from the fallow-deer. He is much larger, and his horns are round, whereas in the fallow species they are broad and palmated. Red deer are now, we believe, almost the only objects of field-sport in this country, and principally in the Highlands of Scotland, where they still exist in considerable numbers. Hounds, however, as in the chase in former ages, are now seldom or never employed—the hunter depending on his gun and his skill in approaching the animal noiselessly. This, which is called *deer-stalking*, is a sport requiring a vast deal of tact, knowledge of the animal's habits, and patience, as whole days are occasionally taken up in stealthily watching an opportunity for a shot. Such is the power of sight, scent, and hearing, that to approach unperceived on a plain is impossible. They must be approached down the wind, and from behind thickets or hillocks. A telescope is required in these difficult manœuvres. When it is impracticable to reach them in this artful manner, attendants drive them into gorges among the mountains, and the sportsman singles out an object for his rifle as it passes his concealed station. A lively work on deer-stalking has been written by Mr Scrope, to which we beg to refer those who are interested in the subject; and some very graphic pictures may also be found in Mr St John's attractive volume on *The Wild Sports and Natural History of the Highlands.*

FOX-HUNTING.

The variety of fox most common in Britain is called the *cur fox*, which is of a brown colour, with generally some white on the breast and belly, and a light tip to the long bushy tail. Foxes go to *clicket* in winter, and cubs are produced in the latter end of March; they breed but once a year, and have from three to eight young ones at a time. In his nature the fox is playful, but rapacious in his appetite, and his predominating characteristic is great craftiness. He usually fixes his abode on the border of a wood, at no great distance from a farmhouse or village; he listens to the crowing of the cocks and the cries of the poultry; he scents them, and chooses the time of his attack with judgment; he conceals his road as well as his design; he slips forward with caution, sometimes even trailing his body, and seldom makes a fruitless expedition. He plans similar encroachments on the nests of birds, rabbit-warrens, &c.; and, in short, is so destructive to poultry, game, and even young lambs, that it is absolutely necessary to take and kill him.

Fox-hunting on a proper scale requires to be conducted with the class of active horses termed hunters, a pack of foxhounds to scent and run down the prey, and terriers to turn the animal from his hole, should he take to earth. A pack of hounds varies from twenty to thirty couples; but besides these, some hounds are always left undrafted into the field. The cost of a well-bred pack is reckoned at from £1000 to £1200, and the annual expense of its keep and management about as much. The huntsman, as the grand leader of the chase, is a functionary of no small importance; he is assisted by two whippers-in, who bring up and take charge of the hounds.

The fox being an early riser, and his scent lying best on the damp grass, he is hunted in early morning; and the first business on taking the field is to ride to and draw cover—that is, bring out the fox from his retreat. At the first sight, the view halloo is given by the huntsman, and all follow the sweeping track of the hounds. It is a rule in hunting never to get before the dogs, or to throw them out any way by a false signal; on the contrary, the great art is to keep them to the scent, and to aid their search. The run is considered the exhilarating part of the sport, and consists of a rapid chase through a broken or rough country, with the hounds in full cry. Then is the ardour of the chase shewn; and it continues till the fox, by some clever manœuvre—such as tracking up a brook—throws the hounds off the scent, and the party is brought to check. The scent and track of the animal being again found, off all go once more in pursuit, but with generally frequent doubts of the result. 'See,' says Beckford, in his enthusiastic style, 'where the hounds bend towards yonder furze brake! I wish he may have stopped there. Mind that old hound; how he dashes o'er the furze! I think he winds him! Hark! they halloo! Ay, there he goes! It is nearly over with him! Had the hounds caught view he must have died! He will hardly reach the cover. See how they gain upon him at every stroke! It is an admirable race; yet the cover saves him. Now be quiet, and he cannot escape us; we have the wind of the hounds, and cannot be better placed. How short he runs! He is now in the strongest part of the cover! What a crash! Every hound is in, and every hound is running for him! That was a quick turn! Again, another! He's put to his last shifts! Now mischief is at his heels, and death is not far off! Ha! they stop all at once: all silent, and yet no earth is open! Listen! Now they are at him again! Did you hear that hound catch him?—they overran the scent, and the fox had lain down behind him. Now, Reynard, look to yourself! How quick they all give their tongues! The terriers, too, are now yelping at him. How close *Vengeance* pursues!—how terribly she presses!—it is just up with him! What a crash they make; the whole wood resounds! That turn was very short! There!—now!—ay, now they have him! Who-hoop!' The chase is over: Reynard is no more; and his *brush* or tail being cut off as a trophy by the huntsman, his unfortunate carcass is thrown to the hounds, and in a few moments destroyed, leaving scarcely a wreck behind.

HARE-HUNTING—COURSING.

Hares are hunted in much the same manner as foxes, the chief difference being, that harriers are employed instead of hounds: both hunt by the scent. Of this branch of field-sports, the writer of the excellent article on Hunting, in the *Encyclopædia Britannica*, makes the following mention:—

'Hare-hunting claims precedence of fox-hunting in the sporting chronology of Great Britain, and we believe of all other countries, inasmuch as a hare has always been esteemed excellent eating, and a fox the rankest of carrion. We gather from Xenophon that it was practised before his day, and he wrote fully three centuries before the Christian era, both hounds and nets being then used in the pursuit. Neither can we marvel at hare-hunting being the favourite diversion

in all nations given to sporting, where the use of the horse in the field had not become common. But we will go a point further than this, and assert, that how inferior soever may be the estimation in which hunting the hare is held in comparison with hunting the fox, no animal of the chase affords so much true hunting as she does, which was the opinion of the renowned Mr Beckford.

'The difficulty of finding a hare by the eye is well known. It is an art greatly facilitated by experience, although not one person in ten who attempts it succeeds. But here we recognise the hand that furnished her with such means for her security; as, from the delicacy of her flesh, she is the prey of every carnivorous animal, and her means of defence are confined only to flight. In going to her seat or form she consults the weather, especially the wind, lying always, when she can, with her head to face it. After harvest, hares are found in all situations; in stubble-fields, hedgerows, woods, and brakes; but when the leaves fall, they prefer lying upon open ground, and particularly on a stale fallow-field; that is, one which has been some time ploughed; as likewise after frost, and towards the spring of the year. In furze or gorse, they lie so close, as to allow themselves nearly to be trodden upon, rather than quit their form. The down or upland-bred hare shews best sport; that bred in a wet marshy district the worst, although the scent from the latter may be the strongest. If a hare, when not viewed away, runs slowly at first, it is generally a sign that she is an old one, and likely to afford sport; but hares never run so well as when they do not know where they are. Thus trapped hares, turned out before hounds, almost invariably run straight on end, and generally till they can run no longer; and they generally go straight in a fog. The chase of the hare has been altered, and rendered less difficult in some degree by the improvement of the hound used in it.

'The difference in the terms used in hare-hunting and fox-hunting is comprised in a few words:—Harriers are cast off in the morning; foxhounds throw off: the hare is found by the quest or trail; the fox by the drag: the hare is on her form or seat; the fox in his kennel: the young hare is a leveret; a fox a year old is a cub: the view holloo of the hare is "Gone away;" of a fox, "Tallyho:" the hare doubles in chase; the fox heads back, or is headed: the harrier is at fault; the fox-hound at check: the hare is pricked by the foot; the fox is balled or padded: the hare squats; the fox lies down, stops, or hangs in cover: the "who-hoop" signifies the death of each.'

Hares are hunted with packs of generally twenty couples of harriers; but whatever number is employed, it is the established rule not to run in upon the hares as soon as discovered in their forms, but to allow them a little space before the dogs are set on. This space is termed 'law.' The hares also must not be pressed upon in the chase by the company; neither are the dogs, in losing scent, to be called on the right path; for this leads them to depend on the sight of the huntsman instead of their own nose. Leave the harriers pretty much to themselves.

Coursing is the chasing and taking of the hare by means of greyhounds, which hunt by the sight only. Among fox-hunters it is considered an inferior kind of sport, but many country gentlemen find in it an exhilarating recreation, and it is patronised by numerous coursing-clubs. 'There is,' says Blaine, 'even a philanthropic character about coursing almost unknown to other huntings. It may be said to offer a kind of refuge for the sporting destitute, for it holds out innocent recreation to those whose means or whose prudence will not allow them to risk either their neck after a fox, or their wealth after a racer. Here the octogenarian, at once labouring under his increased years and his decreased energies, may solace himself with an epitome of former huntings; and further, that the joys of this chase are within the reach of every state or stage of life.'

The greyhound, whose form so eminently adapts him for competing with the hare in a race, requires to be well trained in the art of turning suddenly, and determinedly pursuing his game on a new line of pursuit. His eye should be clear and quick, and his wind good, to enable him to hold out to the last. Greyhounds are delicate in their nature, and require very careful treatment; their lodging must be dry and comfortable; and when taken out in a cold morning, they must be held in leash, with jackets on, ready to let slip. In any case, they are not uncoupled or let go till the hare has been seen and started. A single pair of dogs is generally sufficient for the sport; and betting often ensues as to the *points* in the course. There are numerous rules of ancient and modern date on the subject of coursing. The following are those principally at present in use:—

The hare ought to have from seventy to one hundred yards' *law* before the dogs are slipped, except in particular localities, such as small enclosures.

The points are—a cote, or a go-by, when gained by speed; a wrench, or a turn, when effected by working; and a trip, or a kill.

A cote consists in one dog outrunning the other from the slips, and giving the hare a turn; or subsequently, when one dog, *after turning the hare himself*, and starting in the same position as his fellow, outruns him and makes his point. In either case, it counts two points.

A go-by occurs when a dog gains a clear length on his fellow in a straight run. It is scored two points, and any point subsequently made is scored in addition.

A wrench is when a hare is forced from her line from fifteen to forty-five degrees, and is half a point. A turn, for which one point is scored, is when the hare is forced more than forty-five degrees from her line. If, however, the hare wrenches or turns without being forced by her pursuers, nothing is scored.

A trip or jerk is when a dog lays hold of the hare and looses her again, and counts half a point; whilst the kill is one point, if at all meritorious.

The dog which counts most points gains the course, though in all cases the value of these must be left to the decision of the judge.

The allowances are—for a fall, for losing ground at the start, or the hare bearing decidedly to the other dog, for being ridden over, and for being unsighted through no fault of the dog; but in every case the allowance is to be deducted from the other dog's score.

The penalties are to be deducted from the score of the dog incurring them, and are levied for wilfully standing still in a course, or departing from directly pursuing the hare, or refusing to fence—in all which cases any points made subsequently by him are not to be reckoned.

SHOOTING—GROUSE—PARTRIDGES, ETC.

The leading sports with dog and gun are the shooting of grouse, partridges, and pheasants, which differ in some respects from each other. The first thing to be attended to in either case is having a good fowling-piece or gun; and the second is to know how to use and clean it. Next, the sportsman must be provided with dogs trained to point the kind of game for which they are taken to the field: to take a dog accustomed to point partridges on a grouse-shooting excursion would be improper. The gunpowder employed should be kept very dry in a metal flask, and of proper strength and purity. Patent shot is now commonly used; it is of eight sorts, each numbered, and rises from 83 pellets to 620 pellets in the ounce. Much variety of opinion exists as to the proper size of shot; No. 6 is often used on the moors at the commencement of the season, and as the grouse become wilder, No. 4 or 3 is substituted

The more tender the birds, the smaller may be the pellets or drops.

The following hints to a beginner in shooting are by Hawker and others:—'In raising the gun, let him remember that the moment it is brought up to the centre of the object, the trigger should be pulled, as the first sight is always unquestionably the best. Then send him out to practise at a card with powder till he has got steady; and afterwards load his gun occasionally with shot, but never let the time of your making this addition be known to him; and the idea of it being perhaps impossible to strike his object will remove all anxiety, and he will soon become perfectly firm and collected.

'The intermediate lesson of a few shots at small birds may be given; but this plan throughout must be adopted at game, and continued, in the first instance, till the pupil has quite divested himself of all tremor at the springing of a covey, and observed in the last, till most of his charges of shot have proved fatal to the birds. If he begins with both eyes open, he will save himself the trouble of learning to shoot so afterwards. An aim thus, from the right shoulder, comes to the same point as one taken with the left eye shut, and it is the most ready method of shooting quick. Be careful to remind him (as a beginner) to keep his gun moving, as follows:—before an object, crossing; full high for a bird rising up or flying away very low; and between the ears of hares and rabbits running straight away. All this of course in proportion to the distance; and if we consider the velocity with which a bird flies, we shall rarely err by firing, when at forty yards, at least five or six inches before it. Till the pupil is *au fait* in all this, he will find great assistance from the sight, which he should have precisely on the intended point when he fires. He will thus, by degrees, attain the art of killing his game in good style, which is to fix his eyes on the object, and fire the moment he has brought up the gun. He may then ultimately acquire the knack of killing snap shots, and bring down a November bird the moment it tops the stubble, or a rabbit popping into a furze-brake, with more certainty than he once used to shoot a young grouse in August or a partridge in September.

'Many begin with very quick shooting, and kill admirably well, but are often apt not to let their birds fly before they put up their gun, and therefore dreadfully mangle them; and, I have already observed, are not such everyday shots as those who attain their rapid execution on a slow and good principle.

'If a rival shooter—some stranger—races to get before you, push him hard for a long time, always letting him have rather the advantage, and then give him the double without his seeing you. Having done this, go quietly round—supposing you have been beating up wind—and on reaching the place where you began, work closely and steadily the whole of the ground or covert that you have both been racing over, and you will be sure to kill more game than he will, who is beating and shooting in haste, through fear of your getting up to him, and—if the wind should rise—driving the dispersed, and consequently closest-lying birds, to your beat as fast as he finds them.

'Beware of the muzzle of the gun being kept hanging downwards; when so carried, the shot is apt to force its way from the powder, especially in clean barrels. If it happens that a space of sixteen or eighteen inches is thus obtained, and the gun fired with its point below the horizon, it is ten to one but the barrel bursts. There are other perilous consequences besides those that generally accompany the disruption of a barrel; for the men, horses, and dogs are in perpetual danger of being shot when a gun is carried in the before-mentioned pendent manner.

'When a gun begins to exhibit symptoms of having done its work, the sooner a man discards it the better. An injured barrel or enfeebled lock may prove fatal to the owner or his associates. Accidents occur every day, and very lamentable consequences proceed, from a culpable neglect in retaining arms which should be declared unserviceable and disused.'

Grouse-shooting.—This favourite field-sport, as is well known, commences annually on the 12th of August, when thousands of persons adjourn to remote parts of the country to follow it, with all its toils and privations. Among the varieties of this game are numbered the cock of the wood or capercailzie; the black-cock, heath-cock, black game, or black grouse; the red grouse, moorfowl, or gor-cock; and the white grouse or ptarmigan. Moorfowl are the most common, and seem to be peculiar to Britain. They are very plentiful in the Highlands of Scotland, and by no means scarce in any of the wild, heathy, and mountainous tracts in the northern counties of England and Wales. Red grouse pair early in spring, and lay from six to ten eggs; the young brood follow the hen during the whole summer; and in winter they unite in flocks of forty or fifty. They are seldom seen in the valleys, preferring to keep the summits and sides of the hills, where they feed on mountain-berries and the like. Being generally hatched in April, if the summer has been dry, the young birds will be pretty strong on the wing and ready for the sportsman by the 12th of August.

The best weather for shooting is that which is dry, clear, and warm; wet makes them lie still on the ground. No one need attempt grouse-shooting who is of delicate health, or not well trained by previous feeding and exercise. The labour of walking over heather is most toilsome, and the danger of colds from rain or wet feet considerable. The dress ought to be very strong, without any regard to fineness; stout shoes or quarter-boots are indispensable.

The times of day best suited for grouse-shooting are the morning and evening, when the birds are in quest of food; but few are able to reach their haunts till eight o'clock, when the sport commences. 'To find the birds,' says the author of *Wild Sports of the West*, 'when satisfied with food, they leave the moor to bask in some favourite haunt, requires both patience and experience; and here the mountain-bred sportsman proves his superiority over the less practised shooter. The packs then lie closely, and occupy a small surface on some sunny brow or sheltered hollow. The best-nosed dogs will pass within a few yards and not acknowledge them; and patient hunting, with every advantage of the wind, must be employed to enable the sportsman to find grouse at this dull hour. But if close and judicious hunting be necessary, the places to be beaten are comparatively few, and the sportsman's eye readily detects the spot where the pack is sure to be discovered. He leaves the open feeding-grounds for heathery knowes and sheltered valleys; and while the uninitiated wearies his dogs in vain over the hillside, where the birds, hours before, might have been expected, the older sportsman profits by his experience, and seldom fails in discovering the dell or hillock where, in fancied security, the indolent pack is reposing.'

Our most practical authority on this exciting topic is the *Oakleigh Shooting-guide:*—'Grouse-shooters should separate and range singly; they should have no noisy attendants. In wet weather, one dog is sufficient; we advise rest from eleven till two. The flight of grouse is generally about half a mile. Their favourite haunts, when undisturbed, are those patches of ground where the young heather is most luxuriant. They avoid rocks and bare places where the heather has been recently burnt; at anyrate, they are not to be approached in such localities. It is in young heather that grouse most frequently feed. They are seldom found in the very long thick heather that clothes some part of the hills, until driven there for shelter by shooters or others. It is early in the morning and towards evening that grouse

are to be found in young heather. During the middle of the day, the shooter should range the sunny side of the hill, and avoid plains.

'No species of shooting requires the aid of good dogs more than grouse-shooting, and in no sport does so much annoyance result from the use of bad ones. The best dog perhaps for the moors is a well-bred pointer, not more than five years old, which has been well tutored—young in years, but a veteran in experience. The setter is occasionally used with success, but we prefer the pointer. The latter has unquestionably the advantage when the moors are dry, as it not unfrequently happens that they are in August. If a setter cannot find water wherein to wet his feet every half-hour, he will not be able to undergo much fatigue. Some sportsmen will hunt a couple of mute spaniels for grouse-shooting in preference to any other team of dogs. Of course, when this method is pursued, the birds are never pointed, and the shooter must ever be on the look-out, for the game is generally sprung very near to the gun.' Grouse-shooting, we may add, terminates on the 9th of December.

Partridge-shooting.—Of partridges there are two kinds, the red and gray, the latter being that which is common in this country; the plumage is of a brown and ash colour, elegantly mixed with black; the tail is short, and the figure more plump than handsome. Partridges pair about the third week of February, and sometimes, after being paired, if the weather be severe, they all gather together and form a covey, and are then said to pack. They begin to lay in six weeks after pairing. The female lays her eggs—from twelve to twenty—on the ground, scraping together a few bents and decayed leaves into any small hollow. The young birds begin to appear about the first ten days in June, and the earliest will take the wing towards the latter end of that month. In dry seasons, they are most numerous. So many are the enemies of the partridge, that it is believed never more than a half of those produced come to maturity, and yet there is in general abundance for the sportsman during the shooting-season. The affection of both parents for their young is very remarkable; they lead them out in quest of food, shelter them with their wings, and resort to many tricks to lead supposed enemies away from their broods. Turnip and corn fields are the places which partridges most delight in, especially while the corn is growing; for that is a safe retreat where they remain undisturbed. They frequent the same fields after the corn is cut down, and there feed on the dropped grains, finding a sufficient shelter under cover of the stubble. When the winter comes on, and the stubble-fields are either trodden down or ploughed up, they then retire to the upland meadows, where they lodge in the high grass; they also sometimes resort to the low coppice-woods, especially if they are contiguous to cornfields.

Partridge-shooting commences on the 1st of September, when the birds are strong, and terminates on the 1st of February. In the course of September, the short flights of the coveys, in tolerably well-preserved grounds, afford abundance of sport. In more open districts of country, where there is a wider range, partridge-shooting requires more skill, and the aid of a steady pointer or setter. In shooting either at a flight of grouse or covey of partridges, select a bird on the outside, and fire at it alone; it is only over-hasty or ill-taught sportsmen who let fly indiscriminately at the centre of a covey of birds.

Pheasant-shooting.—Pheasants are a species of birds allied to domestic fowls, and partake of some of their habits; no birds of the game-kind possess such elegant plumage, and few are so large. They breed on the ground, and, like partridges, are fond of nestling in clover; but their chief resort is shrubberies or secluded spots in plantations. The pheasant and its brood, if undisturbed, remain in the stubbles and hedgerows some time after corn-harvest; if molested, they seek the woods, and only issue thence to feed in the stubbles at morning and evening. Besides corn, the birds will live on wild-berries, or any seeds they can pick up. As the cold weather comes on, they begin to fly up at sunset into trees, where they roost during the night.

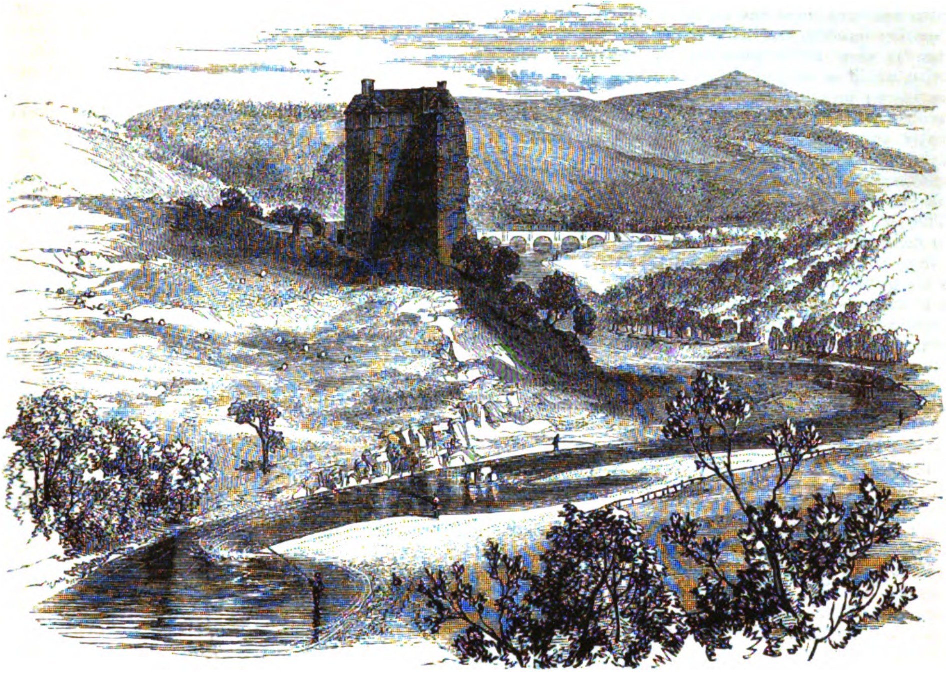
'For shooting pheasants, it often becomes necessary to start very early in the morning, as they are apt to lie during the day in high covert, where it is almost impossible to shoot them till the leaf has fallen from the trees. We can never be at a loss in knowing where to go for pheasants, as we have only to send some one the previous evening, for the last hour before sunset, to watch the different barley or oat stubbles of a woodland country, and on these will be regularly displayed the whole contents of the neighbouring coverts. It then remains to be chosen which woods are the best calculated to shoot in; and when we begin beating them, it must be remembered to draw the springs, so as to intercept the birds from the old wood. If the coverts are wet, the hedgerows will be an excellent beginning, provided we here also attend well to getting between the birds and their places of security. If pheasants, when feeding, are approached by a man, they generally run into covert; but if they see a dog, they are apt to fly up.

'There are very few old sportsmen but are aware that this is by far the most sure method of killing pheasants, or any other game, where they are tolerably plentiful in covert; and although to explore and beat several hundred acres of coppice, it becomes necessary to have a party with spaniels, yet on such expeditions we rarely hear of any one getting much game to his own share, except some sly old fellow, who has shirked from his companions to the end of the wood, where the pheasants, and particularly the cock-birds, on hearing the approach of a rabble, are all running like a retreating army, and perhaps flying in his face faster than he can load and fire.'

It is necessary, in pheasant-shooting, to use a short double-barrelled gun of wide bore, and large shot. Fire at not a greater distance than thirty yards, and only when the bird has risen clear of the bushes; aim is to be taken at the head; but if the pheasant is crossing your path, fire a little before the head, the rapid flight of the animal bringing it in contact with the shot. Towards November, this field-sport—which commences on the 2d of October, and terminates on the 1st of February—may be united with woodcock-shooting.

GAME.

Though, according to law, wild animals are no one's property, yet only certain kinds may be killed without a licence. Those protected from indiscriminate slaughter are called *game*, and are deer of every species, partridges, grouse, pheasants, wood-cocks, snipes, &c. The wild animals not reckoned game are hares, rabbits, crows, rooks, pigeons, all kinds of sea-birds, &c.; any one may kill and appropriate these, provided it be in a highway, the sea-shore, or any other public ground. Game cannot be legally taken or killed in any form without a licence procured from the competent officer of the crown, and a permission from the proprietor of the ground on which the game happens to be. To shoot or hunt without a licence is called *poaching;* to shoot or hunt with a licence, but without a permission, renders the person liable to an action for *trespass.* These game-laws are relics of ancient laws instituted by the Anglo-Saxon and Norman sovereigns for protection of the royal forests.



Angling on the Tweed.

ANGLING.

ANGLING is the art of alluring and capturing fish by means of a rod, line, and baited hook—the bait being made to resemble some object on which the animals naturally prey. The art is so termed, according to some, because an angle, as it were, is formed by the apparatus when held over the surface of the water; while others trace it to the angular shape of the hook, as originally fashioned of wood or bone, such being still the form and materials employed by savage nations. Whatever the origin of the term, the practice of taking fish in this excusably crafty manner, either for profit or for amusement, is of great antiquity, as we may learn from the mention made of it by the prophet Isaiah: 'The fishers also shall mourn, and all they that cast angle into the brooks;' chap. xix. verse 8. As well as fishing with nets, the practice has continued through all ages to the present time, and in almost all countries. In the British islands it has long formed a favourite pastime among every class of society, lay and clerical, and to all presents many features of attraction. As the sport is pursued on the banks of rivers or lakes, in the midst of purely natural scenery, and in weather which invites to out-of-door recreation, everything conspires to render it in a peculiar manner exhilarating and healthful, when indulged in with judicious moderation.

No kind of amusement has been the object of such frequent description as angling. Hundreds of treatises have been written descriptive of the sport in all its departments, and with reference to all varieties of fish and the waters to which they resort. Indeed, several of our rivers are the subjects of illustrated monographs, detailing not only what is peculiar to the angling of their waters, but whatever, in the way of anecdote, tradition, or history, seems likely to render the practice of the 'gentle craft' inviting and agreeable. The first writer of note on the subject, and who has been acknowledged the great father of the angle, was Izaak Walton—born at Stafford 1593, died 1683—who in the year 1653 gave to the world his *Complete Angler*, a work afterwards enriched with additions by his friend Charles Cotton, and which till this day is esteemed not more for the correctness of its details than the singularly happy humour of its apologues, poetical pieces, and disquisitions. According to old Izaak, all recreations sink into insignificance in comparison with angling, which in almost every page he lauds for its moral qualities, and the health and happiness it is calculated to yield.

GENERAL CHARACTERISTICS OF FISH.

The fish which are the object of attention to the angler are all confined to fresh water, and are chiefly found in rivers or small brooks; some are found in lakes and ponds. All, except eels, have a pretty uniform character—more fully detailed under the head ZOOLOGY—

though differing in appearance and size. Their form is suitable in a remarkable way to give celerity and ease of motion—a small head swelling into a thick body, and tapering off towards the tail. Those designed for slower motion are more thick and lumpy in figure. The power of moving quickly, and of buoying themselves in the water, is very nicely provided for by their specific gravity, which is nearly the same as the water in which they move; in other words, they are about the same heaviness as the water which they displace, and consequently they are almost destitute of any feeling of weight. On this account, they are not in the slightest degree encumbered in their movements, and are difficult to tire in their exertions.

The tail is the grand instrument of motion; it is a thin delicate membrane, whose smallest bending to and fro impels the body forward in any required course. The fins are principally required for balancing and regulating the movements of the fish; if any be cut off, the animal loses the power of keeping itself with the back fairly upwards; should it be deprived of the tail, the ability of moving forward is gone, and it lies a hulk at the mercy of its enemies. Not the least remarkable peculiarity in the economy of the fish is the existence of an air-bladder, by the dilatation or contraction of which it possesses the power of rising or sinking in the water, according as it feels inclined. It may be observed that fish, while in water, are constantly moving the gills, which is analogous to the act of breathing. The water sucked in by the mouth, and vented by the gills, contributes a minute portion of air, but enough to keep up the circulation of the blood and sustain life: if we were to tie up the gills, the fish would be immediately suffocated. The blood of fish is cold, being only about two degrees warmer than the water in which they live.

The senses of fish have engaged much attention from naturalists. Their quickest sense is that of sight; but they are destitute of the power of contracting the iris of the eye, so as to accommodate themselves to different degrees of light. In ordinary circumstances, this is of no consequence, as the water diminishes the intensity of light, and the animal has the means of retiring to the bottom, or into holes, to escape the glare of the mid-day sun. As far as experiments have gone to prove, fishes possess little or no sense of hearing; but the senses of taste and smell are largely developed: they are also provided with an appetite of boundless voracity.

'Every aquatic animal that has life,' observes Daniel, 'falls a victim to the indiscriminate voracity of one or other of the fishes. Insects, worms, or the spawn of other tenants of the waters, sustain the smaller tribes; which in their turn are pursued by millions larger and more rapacious. A few feed upon mud, aquatic plants, or grains of corn; but the far greater numbers subsist upon animal food alone; and of this they are so ravenous as not to spare those of their own kind. That there are vegetables in both fresh and salt waters admits of no doubt, and these may furnish food to particular fishes; but those sorts are few—perhaps no one kind can be pointed out that subsists entirely upon them; and although most fishes eat flies and terrestrial worms when they come in their way, yet in the immeasurable waste of waters surrounding this globe, the swarms of fishes are so immense, that the subsistence to be derived from the above sources appears to be altogether disproportioned to their wants, and those of a smaller size seem to constitute the principal food of nearly all the fishes known to us. Charr kept in a pond, if scantily supplied, frequently devour their own young; other fish, that are larger, go in quest of more bulky prey—it matters not of what sort, whether of their own or of another species. If we turn our attention, in this argument, to sea-fish, those with the most capacious mouths pursue almost everything that exists, and often meet each other in fierce opposition, when the fish which has the widest throat comes off with victory, and devours his antagonist.

'The voracious fishes differ widely from the predatory kinds of terrestrial animals; they are neither limited in their number nor solitary in their habits. Their rapacity is not confined to a few species, one region of the sea, or individual efforts. Almost the whole order is continually irritated by the cravings of an appetite which excites them to encounter every danger, and which, by its excess, often destroys that existence which it was intended to prolong. Innumerable shoals of one species pursue those of another through vast tracts of the ocean, from the vicinity of the pole to the equator. The cod pursues the whiting, which flies before it from the bank of Newfoundland to the southern coasts of Spain. The cachalot drives whole armies of herrings from the regions of the north, devouring at every instant thousands in the rear. Hence the life of every fish, from the smallest to the greatest, is but a continued scene of rapine; and every quarter of the immense deep presents one uniform picture of hostility, violence, and invasion.

'In these conflicts, occasioned by the voracity of the different kinds of fishes, the smaller classes must have long since fallen victims to the avidity of the larger, had not nature skilfully proportioned the means of their escape, their numbers, and their productive powers, to the extent and variety of the dangers to which they are unceasingly exposed. To supply the constant waste occasioned by their destruction in the unequal combat, they are not only more numerous and prolific than the larger species, but, by a happy instinct, are directed to seek for food and protection near the shore, where, from the shallowness of the water, their foes are unable to pursue them. These, however, yielding to the irresistible impulse of hunger, become plunderers in their turn, and revenge the injuries committed on their kind by destroying the spawn of the greater fishes.'

That fishes are liable to diseases arising from variations of temperature and other causes, there is no reason to doubt; but few are ever seen dead in the water, there being too many scavengers of the deep to allow of this waste of food. In general, the weak fall a prey to the strong before the period of natural death. It is understood that fishes possess a blunted nervous energy, which renders them almost insensible to any ordinary infliction; and so mean are their reflective faculties, that after escaping from a hook which has lacerated their palate, they will in the next minute catch at a similar bait, and be hooked a second time and drawn from the water. A number of years ago, two young gentlemen, while fishing in a lake in Dumfriesshire, having expended their stock of worms, had recourse to the expedient of picking out the eyes of the dead perch they had taken, and attaching them to their hooks—a bait which this fish is known to take as readily as any other: one of the perch caught in this manner struggled so much when taken out of the water, that the hook had no sooner been loosened from its mouth, than it came in contact with one of its eyes, and actually tore it out. In the struggle, the fish slipped through the holder's fingers, and again escaped to its native element. The disappointed fisher still retaining the eye of the aquatic fugitive, adjusted it on the hook, and again committed his line to the waters. After a short interval, on pulling up the line he was astonished to find the identical perch that eluded his grasp a few minutes before, and which literally perished in swallowing its own eye.

Fishes are exposed, not only to external foes which it requires all their dexterity to elude, but to the torment of parasitical marauders in their own person. Besides creatures which make a lodgment in the intestines, various parasites fix themselves beneath the scales, in the mouth, and upon the gills. Salmon, perch, trout, and other fresh-water fish, are preyed upon in this manner by different species of lice; and as some of these parasites

cannot live in salt water, it has been supposed that one of the reasons for the salmon migrating to the sea is to relieve itself from the lice (*Lernea salmonia*) which have adhered to its gills. The trout louse, or *L. truttæ*, is not unknown to fishers.

FISHING-TACKLE.

The equipment of the angler consists mainly of his rods, lines, hooks, and baits, with the means of keeping them in order, or supplying their place in the event of an accident. To these, dealers have added numerous accessories, more cumbrous than useful, and always more sought after by the holiday angler than the genuine disciple of Walton. As one-half the art depends on proper equipment, we shall describe the leading implements in detail.

The Rod.

This is the chief implement of the angler. It ought to be strong and elastic, and should bend, on being waved, through its upper half, but particularly at the small tapering point. The wood most suitable is hickory or ash, with yew for the upper part, to which a point of whalebone is attached. Young anglers are too apt to select rods measuring from twelve to sixteen feet in length for trout-fishing, when in reality a simple, and not too elastic wand of about ten feet for trout, and eighteen feet for salmon, will amply suffice. Whatever be the length, it must be quite straight, and on all occasions bend back to its original straightness. If there be a single knot in the timber, reject it, for it will certainly snap at the first severe pull or jerk. It should be varnished, to protect it from the action of the water. The rod is not all of one piece; for the sake of convenience, it is divided into three, and sometimes as many as six pieces in the length. These pieces are usually joined by means of screws and ferules; but if this be the plan of the rod offered to your choice, take care to see that these metal junctions do not impair the bending properties of the instrument, or render it too heavy. Rods of a plain kind made in the country are spliced with wax-threads, and these are generally more serviceable than the fine-looking rods manufactured in cities. Listen to what John Younger of St Boswell's—a village on the Tweed—says on this subject: 'To those who reside near the water, I would recommend a rod all of glued and tied joints as best in point of real use, and not so liable to break in the moment of action. Or, indeed, even for travelling, I would prefer tied joints, as wherever a person has time to stop to fish, though only for a day or two, he has at least five minutes to spare for tying his rod in a sufficient manner. Rods are often breaking at brass joints; and those who use them, instead of bringing in a back-load of fish, are constantly arriving home from the water, telling you: "I've broken my rod!" Such sickening news may generally be, prevented by tied joints.'

At the bottom of the rod, where it is grasped by the hand, a brass reel or *pirn* is attached, and on this the line is wound. It should be simple in its mechanism, so as to allow of expeditious winding or unwinding. The line is conducted from the reel to the upper termination through small wire-loops, in Scotland called *mylies*, which are fixed to the rod; these must be in an even line when the pieces of the rod are joined together, and be about a foot asunder. In *fashionable* rods, the mylies are small rings held by wires to the rod, and they conveniently fall flat when the rod is not in use. Good serviceable rods require no such elegance of design. The angler who is skilled in his art cares nothing for finery of apparatus, and will pull out dozens of fish in a day with an instrument which many would think not worth the carrying. Indeed, one of the best day's sport ever we enjoyed was with a sapling ash, lithe and green, from the banks of the river over which it was plied with such memorable success.

Lines.

These should be long, smooth, and flexible, and of a material which will not be easily injured by wet. These qualities are found in lines made of horsehair and gut, which we recommend in preference to any other. The part of the line which is wound on the reel, and goes along the rod, is called the *reel-line;* and being designed to be let out only on occasions when a fish darts off with a hook in its mouth, it need not be so thin and light as the bulk of the portion termed the *casting-line.* A better cast can be made with a heavy, than with a very light line, as it is not so apt to be affected by the wind. The reel-line, which may be about thirty yards in length for ordinary trout-fishing, and about sixty for salmon, is formed by spinning together horsehairs, so as to make a fine even cord. As it is troublesome to make, it should be purchased from a respectable dealer in fishing-tackle.

The casting-line, which is united by a loop to the reel-line, may be also of horsehair, but of a smaller texture and lighter in weight. It should be five lengths of hairs in extent, the uppermost length being eight hairs in thickness, and gradually tapering to the lowest length. To the lower end of this casting-line is added the *gut-line*, which is the part that actually falls upon the water, and therefore requires to be very fine. It consists of a series of strong gut, and to it is attached the short lengths, or casts of gut on which are the hooks. In some instances, casting-lines are altogether made of gut, but those of hair are better, on account of their greater elasticity.

On the article gut, Mr Stoddart, in his *Art of Angling*, has the following observations: 'This article, originally imported from the East, and now brought in considerable quantities from Spain and Italy, is, as far as we have been able to learn, fabricated from the male silkworm in a state of decomposition. The operation is principally conducted by children, and consists in removing the external slough of the worm with the fingers, elongating at the same time the gluey substance which composes its entrails. To do this properly, requires some care and attention. Should the worm be kept too long, a hard crust forms itself over it, in destroying which the application of the nail is necessary; hence the gut becomes flattened, and loses much of its value. The sinews of herons and other birds are also manufactured in Spain into a sort of gut, and are much used, although unwittingly, by our salmon-fishers. Worm-gut varies in length from nearly two feet and downwards. We have seen, however, an article very closely resembling it from the Archipelago, which measures at least a yard and a half. This is not to be confounded with sea-weed, although a vegetable fibre, and drawn out of a plant. It is much stronger, and better suited for angling. The inhabitants of the Greek islands use it for catching mullet, and will often toss a fish some pounds' weight over their heads by a thread or two. We ourselves have found it excellent for the larger sorts of tackle. Animal gut is, however, more generally used, and better adapted for trouting. It ought to be small, round, and transparent, without any flaw or roughness. When worn or disordered, the application of a piece of India-rubber will at once renovate it. In joining threads together for the purpose of making casts, the single knot properly drawn is quite sufficient. One should avoid clipping the useless extremities too closely in this operation, as in that case the knot is somewhat liable to give way. Gut, to keep well, should be moistened with fine oil—almond or olive—and stored in oiled paper.'

To these recommendations we may add, that lines of all kinds should be kept dry. On returning from a fishing-excursion, draw out the line, and let it be thoroughly dried by waving in the air before being wound up or laid aside. When to be again used, look it over, giving it a gentle tug here and there to try its strength, and repair

damaged parts. On coming to the water-side, and just before throwing, allow the casting-line to be wetted in the water, and this will at once give it smoothness and elasticity.

Hooks.

These are small instruments made of tempered steel, and of whatever size, they require to possess the qualities of lightness and great strength. They have been always principally manufactured at two places—Kendal in Westmoreland, and Limerick in Ireland. The Kendal circular bends, as they are called, are reckoned the best hooks of a small size, while the Limerick hook is preferable for salmon. Many of the fish-hooks of ordinary English makers are worthless. Hooks range in size from about an inch and a half in length down to a quarter of an inch, with a proportional diminution of thickness. Some makers number them from No. 10, the smallest, to No. 20, the largest; while others number from 1, the largest, to 14, the smallest. The Limerick hooks are denoted by letters, commencing with A, and so on. In purchasing hooks, see that the body is of equal thickness throughout, and that the barb is boldly yet firmly set. Try their power of resistance by forcing the bend with the fingers, and urging the point against the thumb-nail. Hooks for fly-fishing should be thinner in the shank than those designed for bait. An angler should keep a small stock of hooks of various sorts, to be ready on all emergencies; with the tackle to which they are attached, they require to be kept very dry.

Landing-net—Gaff—Drag-hook.

The *landing-net* is considered in England a necessary implement for an angler, but in our opinion, they must be poor hands at fishing who cannot drag a trout or any similar small fish from the water after hooking it without resorting to such a cumbrous apparatus. Perhaps it is found to be essential, in consequence of the feebleness of the rods and tackle usually employed. It consists of a small bag-net stretched on a hoop at the extremity of a pole four or five feet in length. Mr Blaine, in his *Encyclopædia of Rural Sports*, seems to think a landing-net of first importance; and for the use of tyros in the art, he gives the following directions: 'In fly-fishing, when the line is long, and there is not much space to step backward, or the reel clogged, it is necessary sometimes to lay hold of the line with one hand; but this should be done with great caution, and then only after the fish is well-nigh spent, or one struggle may carry away line, hook, and fish. In all other cases, avoid touching the line, if possible; but having sufficiently played the fish, whether taken by bottom or by fly-fishing, bring him within reach of the landing-net, and then carefully conduct or slide the net obliquely under the foreparts of his body, which, if the fish be completely exhausted, will fall into it; but if he has still sufficient vigour, it will be prudent rather to slide him over the net than the net under him. It must have occurred to every angler to have supposed a trout or salmon to be completely spent, which, the moment he has been touched by the net, or has even caught sight of the fisher, has sprung off with most annoying violence. Against such an accident, it is prudent to be ever prepared by keeping the rod in an upright position, acting on a tightened line, but yet so disposed that it can run at liberty if required. When the head and shoulders of the fish are once fairly within the net, a slight turn of it will take in the whole body, and the net being then kept horizontally, will insure his safety; for with the head downwards, he cannot disengage himself from the net: but if he be received tail foremost, as is sometimes done in deep waters, from overhanging banks, &c., beware of his plunges.'

The *gaff* is another aid to landing fish, and is employed in cases in which the landing-net would be too small. It is used chiefly for landing salmon, and consists of a peculiarly shaped hook at the end of a staff. When the salmon flounders about, and incommodes the fisher, he is expected to secure the animal, and prevent it from breaking his line and rod by hooking it with the gaff at the gills, the tail, or any part he can conveniently lay hold of.

The *drag-hook* is an implement with three bent prongs or hooks, with a long cord-line attached. It is used for casting into rivers to clear away any object at the bottom upon which the hook is caught. We pity the angler who attempts fishing in weedy puddles requiring such a clearer of hinderances.

Angler's Pocket-book, &c.

The angler's equipment is completed by the addition of a basket for holding his fish, which is slung on the back by a shoulder-belt; also a pocket-book for holding hooks and other trifles; and a round flat tin box for his fly-casts. Many carry their supply of fly-casts wound round their hat, and some keep them within the leaves of their pocket-book. This pocket-book, which is the storehouse of all kinds of odds and ends—we have seen a good one made out of an old pocket almanac—should have two or three pockets for holding an assortment of hooks, silk thread, stuff for making flies, gut, wax, small cord, fly-nippers, scissors, &c.—all to be used in case of breakage of tackle or rod, or any other accident. In fishing for perch, gudgeons, bream, &c., a small float is often used. Floats are made of cork, quill, reed, and other materials; and a choice, according to circumstances, can be added to the contents of the pocket-book.

For an angling dress, all finery is worse than useless. Fish are easily scared with the appearance of any light or showy object on the banks. Let the angler, therefore, dress himself in a plain dull-coloured suit, with a hat equally sober in its aspect; and let him use only strong shoes or boots which will not be injured by water. A suit of gray-coloured Tweed, with a felt or flap hat, is at present reckoned orthodox; and to these we may safely suggest the addition of a pocket-flask, to be filled at the outset of the day's excursion according to the taste of the bearer.

Baits.

A bait is any substance put upon a hook to act as a lure to the fish; and when used, the baited hook is dropped into, and allowed to sink in the water, instead of being kept near or upon the surface, as in the case of fishing with fly. The materials, living and dead, used for bait are very numerous; but the leading kinds are worms, maggots, minnows, insects, and salmon-roe. The hook employed in either case is tied by the shank to the gut with waxed silk, and the preparation is therefore not at all difficult. When dressed to the gut, it is called bait or worm tackle.

Worms used for bait are of various sorts; but that which is most commonly employed is the lob or garden worm, a long reddish-coloured reptile found in abundance in many gardens, grass-plots, under old cow-droppings in fields, and in any rich old soil. They may be dug up with a spade, or caught while crawling from their holes at twilight, and particularly after heavy showers. 'He who seeks them,' says Daniel, 'must move cautiously without noise, or they will quickly retreat into the earth; draw them gently out of their holes without nipping; those that sever in taking must be thrown away, as they will soon become putrid, and infect the others. When as many are collected as are wanted, having plenty of good moss freed from dirt, dip it into clean water, and wring it nearly dry; put it into an earthen pot proportioned to the quantity of worms, laying it regular, and forcing it down with the hands; strew the worms on the surface, after dipping them in clear cold water to rid them of the soil that may adhere to them; such as are not injured will soon bury themselves in the moss, and those that do not, must the next morning be picked off as useless. They must be inspected every three or four days, the dead ones removed, and have fresh moss, or that wherein

they have been kept, well washed and picked, and the water squeezed out at least once a week. They must be so placed, summer and winter, as to be safe from the extremity of the weather at both seasons. In a week's time, they will be fit for use; and upon the angler coming home from fishing, he will return from his worm-bag into the pot those which he has not used. By observing the above carefully, they may be kept a month in summer, particularly by now and then giving them, drop by drop upon the moss, a small quantity of new milk and the yolk of an egg well beaten together and warmed, so as to thicken it; but when a stock of lob-worms is meant to be retained for a considerable length of time, a large vessel must be filled half or three-quarters full of good mould, in the middle of which is to be placed some moss or old coarse linen cloths, hopsack, or rags wetted. In hot dry weather, clean water must be sprinkled upon the earth with a watering-pot, so as to keep them moist, but not wet; they may thus be preserved as long as is requisite; and a week before angling, what are wanted may be drawn from the store, and put into moss to scour themselves.' *Fresh* worms, however, are now considered best for salmon. Another worm, which is found in dunghills, called the *brandling*, from its striped appearance, forms a good bait, but it is seldom used.

Maggots, or the larvæ of insects, as is well known, are found on fly-blown meat or any putrid animal substances: very fine ones are procured from game in a *high* condition. Daniel calls these creatures *gentles*, and describes them as of great virtue in certain kinds of fishing. 'Gentles,' he observes, 'may be procured almost at any time at the tallow-chandlers, and should be kept in oatmeal and bran, as bran by itself is too dry. Those who live in or near London may buy them in proper condition for the day on which they wish to use them; but for the accommodation of those who reside in the country, remote from such convenience, the best modes of breeding them will be here mentioned, in order to prevent disappointments. Coarse fish, such as *chub* and *roach*, may be laid in an earthen pot, in the shade, and will soon be fly-blown. When the gentles are of the proper size—but not before—put some oatmeal and bran to them, and in two days they will be well scoured, and fit to fish with; in about four more, they become hard, assume a pale-red colour, and soon after change to flies. The red ones should not be thrown away, as frequently roach and dace take these with a white one, in preference to all other baits. Some have recommended a piece of liver suspended by a stick over a barrel of clay, into which the gentles fall and cleanse themselves; but clay will not scour them, and, besides, they fall from the liver before they have attained their full size. The before-mentioned is a less disgusting plan. For a short time after oatmeal and bran are put to the gentles, the fish in which they are bred will be found perfect skeletons, and may be thrown away; however, if they are to be bred from liver, it should be scarified deeply in many parts, and then hung up, and nearly covered over, as in that way the flies will blow it better than when wholly exposed. In two or three days, the gentles will be seen alive; the liver is then to be put into an earthen pan, and there remain until the first brood are of full growth. A sufficient quantity of fine sand and bran—letting the liver remain—is then to be put into the pan, and in a few days they will come from the flesh, and scour themselves in it. The liver should then be hung across the pan, and the latter brood will soon drop out, and be fit for use; and by thus breeding them in October, and keeping them a little warmer than those bred in the summer, until they arrive at their full growth, and afterwards putting them in the same pan into a dampish vault, they may be preserved for winter-fishing. Those bred in summer, but for the bran and sand, would soon sink into a dormant state. The skins take on a blackish red, full of white matter, and shortly after become flies. Those produced in autumn, from whatever substance, will continue in this state all the winter, provided they can shelter themselves under the surface of the earth in fields, gardens, &c.; and in the warm weather of the ensuing spring they change into flies, thus preserving their kind from year to year. Gentles are so universal and so alluring a bait, that the angler should never be unprovided with them. Trouts have been taken with them in clear water, when they have refused all kinds of worms and artificial flies.'

Caddis, or *cad-bait*, is another kind of larva, inhabiting pieces of straw, or little cylinders formed of bits of stick or sand at the sides of rivers. They are always most deadly in the rivers from which they have been taken, and are found to answer best in tributary streams. Daniel, in making some observations on this kind of bait, says: 'Some of them enclosed in a very rough shell, found among weeds in standing waters, are generally tinged green; others are bigger than a gentle, and of a yellowish hue, with a black head: they form an excellent bait, and are found most plentifully in gravelly and stony rivulets, and by the sides of streams, in large rivers among stones.

'To collect them, turn up the stones, and the best will adhere to them. When the quantity wanted is obtained, put them into a linen bag for five or six days, dip them, together with the bag, into water once a day, and hang them up; they will then turn yellow, become tough, and fitter for angling than when first got from the brook. If meant to be kept long, they must be put into a thick woollen bag, with some of the moist gravel or sand from the same rivulet whence they are taken; they must be wetted twice a day, but oftener in very hot weather. When you carry them abroad, fill the bag with water, and holding the mouth of it close, let the water run from them; in this way they may be kept three weeks. Another way of preserving them is by placing them in an earthen pot full of river-water, with some of the gravel they were bred in at the bottom; but the preceding method is preferable. Some use bait-pans of different sizes for insects, the tops punched full of holes, not so large as to admit of their escaping when placed in the river, which not only keeps them cool, but supplies them with aliment in the fresh water; some keep them in moss in a woollen bag on a damp floor, taking care that the bag retains a proper moisture. A third mode of preserving caddis, and also grasshoppers, caterpillars, oak-worms, or natural flies, is to take the green withy bark from a bough six or seven inches round, and about a foot in length: turn both ends into the form of a hoop, and fasten them with a large needle and thread; stop up the bottom with cork, and bore the bark full of holes with a red-hot wire; tie over it a colewort leaf, and lay it in the grass every night. In this manner caddis may be preserved until they turn to flies. When grasshoppers are to be preserved in the case, some grass must be put into it.

'In angling with caddis, the line, when all out, should be as long as the rod, for three lengths next the hook, of single hairs, with the smallest float, and the least weight of lead that the swiftness of the stream will allow to sink; and that may be aided by avoiding the violence of the current, and angling in the returns of a stream, or in the eddies betwixt two; which are also the most likely places wherein to kill fish, either at the top or bottom. The caddis may be at times, with very good effect, joined to a worm, and sometimes to an artificial fly, to cover the point of a hook; and also two or three together may be put in upon the hook. It is always, however, to be angled with at the bottom, especially when by itself, with the finest tackle, and at all seasons forms a most holding bait for trout and grayling.'

Minnow bait.—Minnows are a small fish, from an inch to two inches in length. They swim in flocks, and may be captured by a hoop-net on the end of a staff,

or more simply, by a crooked pin baited with a small worm. Anglers generally hire a boy to catch a quantity of them. The tackles used for minnow bait are various in their formation: some are single hooks; others, a pair of hooks dressed back to back; and a third kind are a series of pairs, one above another. We cannot do better than give Mr Stoddart's description of these deadly instruments, and the mode of baiting them. He alludes to Kendal hooks:

'The most simple, and in some places the most deadly, is a common single bait-hook. This we insert through the back of the minnow, and drawing it out, run below the gill, allowing the barb to protrude from the mouth; we then tie up the tail along the gut, either with a piece of silk thread, or more expeditiously with the gut itself, hitched over the part. This is angled with in the same manner as the worm, allowing plenty of time for the fish to gorge. A tackle similar to it may be used in standing-pools or lochs. Here, however, the shank of the hook—a long one—is loaded, and the bait allowed to descend rapidly towards the bottom. Large cautious fish are sometimes taken by this method of angling. Of all minnow-tackles, that with swivels is the commonest and most agreeable to employ. There are many ways of constructing it. Two of these we shall mention as preferable to all others. One is simply a large hook, No. 11, fastened to good round gut with two smaller ones, No. 7, tied back to back above, and looped in the dressing, so as to slide along, and shorten or lengthen the tackle to the dimensions of the bait. In using it, enter the lowermost hook through the mouth, and bring it out near the tail of the minnow; insert one of the hooks on the slider, through its lips, noticing that the fish be slightly curved, so as to spin properly. The other tackle is composed of six hooks, No. 7, dressed in pairs, and is angled with only when the trout are in a taking mood. Two or more swivels are required for both of these contrivances—the lowermost fastened about two feet or so above the bait. Leaden pellets may also be used, but many think them unnecessary. Some anglers attach behind the whole apparatus an extra hook, No. 12 or 13, dressed upon a hog's bristle, which, should the trout miss the minnow, is apt to catch him, when retiring, by the middle or other part of the body. This is a superfluity, and, like many superfluities, does more harm than good, alarming the fish without securing them. Tackle for trolling with parr or small trout ought to be constructed on the same principles as the minnow-tackle; only the hooks should be larger, and dressed upon gimp instead of gut. Snap-hooks, also, are in use for this kind of angling. Small silk cord oiled will be found the best trolling-line.'

The perfect insects used for baits are grasshoppers, crickets, day-flies, spring-flies, May-flies, humble-bees, and various others. The ephemeræ, or those fragile creatures that live but for a day or even a few hours, and therefore called day-flies, are found sporting by the low banks of rivers in warm weather, and form a taking bait for trout and some other fish.

Salmon Roe.—The efficient use of this as a bait is a modern discovery, and has added largely to the angler's means of capturing the finny tribes. It is prepared for use by salting it a little, and drying it to a state in which it will keep.

Mr Boyd, Secretary of the St Ronan's Angling Club, who has written a good deal upon this, as well as on other subjects connected with angling, makes the following observations upon roe-fishing: 'Fishes are acutely sensible to the touch; the sense of smelling, for which appropriate nerves are elaborately distributed, gives them the faculty of detecting the existence of food or enemies at great distances. The roe-fisher will therefore find that the previous baiting of the pool, before commencing operations, will much add to his success.' He goes on to say that though he has met with great success during floods, still this bait answers well whilst the streams are much reduced, some of his most successful takes having occurred while the rivers were in this state. He says: 'When the rivers continue in this state (reduced), two small hooks, with their shanks shortened, and tied back to back, ought to be used, and so baited as to completely envelop the hooks, which must be attached to gut of the finest description; and as long as the water remains small, a little before sunrise will be found the most deadly time for killing the larger description of trout. The Limerick-shaped hooks I consider the best for roe-fishing; in particular when a single hook is used, which ought to be invariably the case in turbid or swollen waters. The only objection to the roe cured in the pea, is that of its being not sufficiently tough upon the hook, and therefore stolen with such ease by the fish as to require frequent rebaiting. In this respect, the pasted roe has the advantage, and at the same time equally killing as that cured in the pea. The sea-trout roe will be found much more durable as a bait than that of the salmon, in consequence of its natural toughness, and in no degree less efficacious. To be successful in roe-fishing, very much depends upon the quality of the roe, which ought invariably to be cured so as to retain its natural fishy smell; and to preserve this, it will require to be regularly kept in a dry situation, and exposed as little as possible to the air. The size of the bait ought never to exceed that of a small coffee-bean, and to be put on the hook in a globular form, which fish most readily gorge without detecting the steel. In all my experience in fishing, which has been considerable, I have almost invariably found, when using the pasted or gummy roe, that, by allowing the trouts time to swallow the bait, I seldom or never failed in killing the fish. Salmon, and more particularly sea-trout, take roe readily in turbid water. The bait, however, will require to be considerably larger than that recommended for the common trout.'

Artificial Flies.

Hooks dressed up so as to bear something like a resemblance to actual live flies, are by far the most important lures employed by the angler. The principal materials employed in dressing are light portions of cock's hackle or other feathers, to form wings, the fur of a hare's ear or some other substance to make the body, and waxed silk thread, by which the whole is tied in an artful manner on the shank of the hook. A whole sheet might easily be filled with descriptions of artificial flies suitable to different fish, waters, and seasons; but the bulk of what has been written by Walton, Daniel, and many others, is now considered superfluous, experienced fishers having arrived at the conclusion, that fishes in general are such eager and heedless fools as to be satisfied with a very limited choice of deceptions. The author of the article Angling, in the *Encyclopædia Britannica*, has some clever remarks on this branch of the art:

'As simulation,' says he, 'consists in the adoption or affectation of what is not, while dissimulation consists in the careful concealment of what really is—the one being a positive, the other a negative act; so the great object of the fly-fisher is to dissimulate in such a manner as to prevent his expected prey from detecting the artificial nature of his lure, without troubling himself by a vain effort to simulate or assume with his fly the appearance of any individual or specific form of insect life. There is, in truth, little or no connection between the art of angling and the science of entomology; and therefore the success of the angler, in by far the greater proportion of cases, does not depend on the resemblance which subsists between his artificial fly and the natural insect. This statement is no doubt greatly at variance with the expressed principles of all who have deemed fishing worthy of consideration, from the days of Isaiah

and Theocritus, to those of Carrol and Bainbridge. But we are not the less decidedly of opinion, that in nine instances out of ten, a fish seizes upon an artificial fly as upon an insect or moving creature *sui generis*, and not on account of its exact and successful resemblance to any accustomed and familiar object.

'If it is not so, let us request to be informed upon what principle of imitative art the different varieties of salmon-fly can be supposed to bear the most distant resemblance to any species of dragon-fly, to imitate which we are frequently told they are intended? Certainly no perceptible similarity in form or aspect exists between them, all the species of dragon-fly, with the exception of one or two of the sub-genus Calepterix, being characterised by clear lace-like pellucid wings, entirely unadorned by those fantastic gaudy colours, borrowed from the peacock and other "birds of gayest plume," which are made to distinguish the supposed resemblance. Besides, the finest salmon-fishing is frequently in mild weather during the cooler seasons of the year, in autumn and early spring, several months either before or after any dragon-fly has become visible on the face of the waters, as it is a summer insect, and rarely makes its appearance in the perfect state until the month of June. If they bear no resemblance to each other in form or colour, how much more unlike must they seem when, instead of being swept like lightning down the current, as a real one would be, the artificial fly is seen crossing and recrossing every stream and torrent with the agility of an otter and the strength of an alligator! Or, darting with regular jerks, and often many inches under water, up smooth continuous flows, where all the dragon-flies on earth, with St George to boot, could not maintain their place a single second! Now, as it is demonstrable that the artificial fly generally used for salmon bears no resemblance, except in size, to any living one—that the only tribe which, from their respective dimensions, it may be supposed to represent, does not exist in the winged state during the period when the imitation is most generally and most successfully practised—and if they did, that their habits and natural powers totally disenable them from being at any time seen under such circumstances as would give a colour to the supposition of the one being ever mistaken for the other—may we not fairly conclude that, in this instance at least, the fish proceed upon other grounds, and are deceived by an appearance of life and motion, rather than by a specific resemblance to anything which they had previously been in the habit of capturing? What natural insect do the large flies, at which sea-trout rise so readily, resemble? These, as well as grilse and salmon, frequently take the lure far within the bounds of the salt-water mark; and yet naturalists know that no such thing as a salt-water fly exists, or at least has ever been discovered by their researches. Indeed, no true winged insect inhabits the sea. What species are imitated by the palmer, or by three-fourths of the dressed flies in common use? An artificial fly can, at the best, be considered only as the representative of a natural one which has been drowned, as it is impossible to imitate the dancing or hovering flight of the real insect over the surface of the stream; and even with that restricted idea of its resemblance to nature, the likeness must be scarcely perceptible, owing to the difference of motion and the great variety of directions in which the angler is obliged to drag his flies, according to the nature and special localities of the current, and the prevailing direction of the wind.

'We are therefore of opinion that all, or a great proportion of what has been so often and sometimes so well said about the great variety of flies necessary to an angler—about the necessity of changing his tackle according to each particular month throughout the season—about one fly being adapted solely to the morning, another to noonday, and a third to the evening—and about every river having its own particular flies, &c., is, if not altogether erroneous, at least greatly exaggerated and misconceived. That determinate relations exist between flies of a certain colour and particular conditions of a river, is, we doubt not, true; but these are rather connected with angling as an artificial science, and have but little to do with any analogous relations in nature. The great object, by whatever means to be accomplished, is to render the fly deceptive; and this, from the very nature of things, is continually effected by fishing with flies which differ in colour and appearance from those which prevail upon the water; because, in truth, as we shall afterwards have occasion to shew, none else can be purchased or procured. Even admitting for a moment the theory of representation, when a particular fly prevails upon a river, an artificial one in imitation of it will never resemble it so closely as to appear the same to those below (that is, the fish); on the contrary, a certain degree of resemblance, without anything like an exact similitude, will only render the finny tribe the more cautious through suspicion, while a different shape and colour, by exciting no minute or invidious comparisons, might probably be swallowed without examination. Indeed, it seems sufficiently plain that where means of comparison are allowed, and where exact imitation is at the same time impossible, it is much better to have recourse to a general idea than to an awkward individual representation.'

Mr Stoddart, one of our most experienced anglers, entertains a similar opinion. 'The colours of water and sky,' he observes, 'are the only indicators which can lead us to select the most killing hook, and even these are often deceptive. We have fished in one stream where dark, and in the next, red flies took the lead. There is no trusting to the fancy in certain places. On Tweed, we have seen it veer about like the wind, in one moment, without a note of preparation. Most rivers, however, are more steady; and when the water is of a moderate size, may be relied on with at most two sorts of flies all the year round. For ourselves, our maximum in every Scottish stream is reduced to only four descriptions of artificial flies, with one or other of which we engage to catch trout over all the kingdom. Knowledge and practice have convinced us of the needlessness of storing up endless and perplexing varieties, which some do, in order to appear knowing and scientific.'

The following descriptions of flies and spiders have been highly recommended to us by Mr Boyd, an old and experienced angler, and who has found them to be most killing, particularly in the rivers and tributaries of the border counties of Scotland. He says: 'The flies and spiders with which we have achieved our greatest takes, were purchased at Mr Lang's fishing-tackle establishment, South Hanover Street, Edinburgh.* We may add with much truth, that we have invariably found the *spiders* more deadly than flies; and with regard to salmon flies, we are decidedly of opinion that no one, however ingenious, can make a fly, be the colour what it may, that will not kill, provided he keeps within bounds with regard to size. We have, however, found from extensive experience, that the two flies here represented and described, are superior to all others we have hitherto tried.

Salmon Flies.

'They are dressed with the following materials:

'No. 1. Tail—crest-feather from golden pheasant; tip—gold tinsel and orange silk, with two turns of ostrich herl; body composed of claret-coloured pigs' wool and mohair mixed, with a little pigs' wool at the head, of a light-blue shade; wound with silver tinsel and dark-red

* The originals from which the drawings on next page were prepared, were furnished by Mr Lang.

hackle, with blue jay's feather for shoulders; wings—from the teal-duck or widgeon, distinctly marked or barred; head—of black ostrich herl.

1 2

'No. 2. Tail—crest feather from golden pheasant; body composed of pigs' wool and mohair mixed, of a dark-cinnamon shade; wound with silver twist and dark-red hackle; shoulders composed of breast-feather of the argus pheasant; wings composed of golden pheasant tippet or neck feathers, distinctly marked teal, four fibres of blue and red macaw tail-feathers, with pairs of wings from the brown and black barred feathers of the peacock wing surmounting the whole; a blue feather from the kingfisher or blue chatterer on each side of the wings; feelers—from blue and buff macaw tail-feathers; head—black ostrich herl.'

Trout Flies.

Nos. 1 and 2 of the flies, and No. 1 of the spiders in the following list, are represented in the annexed wood-engraving; and we may here mention that the practice of fishing for trout with heavily dressed flies is now considered by the best anglers to be a mistake, especially in streams. Our present authority uses only thinly dressed flies or spiders, and likewise recommends the practice of *frequent* casting; his reason being, that trout almost invariably seize the lure the instant it reaches the water, seldom waiting till the casting-line has swept the stream. He also recommends fishing up the stream, as by that means the fish are less likely to see the angler. To avoid unnecessary fatigue to the arm, the rod should be light and short.

Flies.—No. 1. Wings formed of feathers from the wing of the chaffinch, with a black hackle, tied with slate-coloured silk.

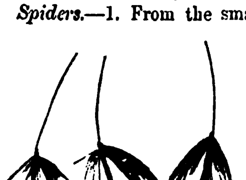
2. Wings composed of woodcock or partridge feathers, and red hackle, tied with yellow silk.

3. Wings formed of the corn-bunting, with a red hackle wound round close to the head, tied with orange-coloured silk.

4. Wings formed from the speckled feather of the teal, with a black hackle wound round close to the head, tied with brown silk. The same wing with a red hackle, tied with yellow silk, also makes a killing fly.

5. Wings from the feathers of the dotterel; body and hackle same as No. 2.

Spiders.—1. From the small feather of the dotterel wing, tied with yellow silk thread.



1 2 1

Flies. Spider.

2. From the small glistening feather taken from the outside of the shoulder of the starling's wing, tied with yellow silk thread.

3. From the neck-feathers of the hill-partridge, tied with yellow silk thread.

4. From the black hen-hackle, tied with small black silk thread.

5. From the blue hen-hackle, tied with yellow silk thread.

6. From a small red cock-hackle, or the small feather of the landrail's wing, tied with yellow silk.

Mr Stoddart offers the following explicit directions for fly-dressing; and every one who wishes to become an adept should make himself master of this portion of the art:

'Our materials for the making up of flies are as follow: Hooks, and small round gut; a pair of brass nippers for twisting hackles; a point for dividing the wings; a pair of fine scissors; orange, yellow, and green silk thread of all sizes; good cobbler's wax enclosed in a piece of soft leather; a hare's ear; some brown wild-drake, teal, and pheasant feathers; the fur of a mouse, squirrel, and water-rat; a few wings of lark, snipe, landrail, and starling; and, lastly, red and black hackles, taken from the neck and head of an old cock at Christmas: these should be fully formed, and free from softness. Plovers' herls, and those of the peacock, are used by some, yet we deem them superfluous; as also tinsel, except for large flies.

'Commencing your operations, the first step is to lay out the intended wings and body before you; wax your silk, and applying one end of it to the gut and hook together, wrap them both round four or five times, commencing a little below the end of the shank, and proceeding downwards; you then fasten, by drawing the disengaged end of the thread through under the last turn of the wrapping. Work the silk upwards to where you commenced, then take your wings, which are still unseparated, and lay them along your hook, so that their extremity or tips shall reach its curve; twirl the thread twice round the upper part, which lies along the shank top; then taking it under, press firm, and clip off the unnecessary portion of the feather; divide with your point or penknife, so as to form the two wings; take up the silk betwixt them, and wrapping again round at the head, bring it back crosswise; then lift your hackle, and lay the root of it down along your hook; whip the thread over, as far as your first fastening; seize the top of the hackle with your nippers, and whirl it round in the same manner; fasten and lengthen the body to your liking with fresh floss silk; fasten once more, and your fly is made. This last fastening ought, in our opinion, to be the same as that used in arming bait-hooks, for which we quote Hawkins's directions:—"When you are in about four turns of the bend of the hook, take the shank between the fore-finger and thumb of the left hand, and place the silk close by it, holding them both tight, and leaving the end to hang down; then draw the other part of the silk into a large loop, and with your right hand turning backwards, continue the whipping for four turns, and draw the end of the silk—which has all this while hung down under the root of your left thumb—close, and twitch it off." When the body of your fly is required to be of hare's ear or mouse-skin, pull out a small quantity of the fur, and lay it along the silk, after the wings are formed; twist together, and then wrap as if the thread were bare, and fasten as above. In making flies, keep all tight, guard against heavy wings and much dubbing; the fibres of your hackle ought to be short, and lie near the head of the fly; they are intended to resemble legs, which in the real insect are always so placed. Such is our method of fly-dressing, commendable both for its simplicity and expedition. It differs, we find, somewhat from that generally practised, being in a manner self-taught, and not encumbered with any unnecessary display.'

Having now described the various parts of the angler's apparatus, and the lures which he generally employs, we proceed to shew how he is to practise his craft when fully equipped for the purpose.

PRACTICE OF ANGLING.

There are two distinct kinds of angling—bait-fishing and fly-fishing, and these are variously practised according to the depth, current, and state of the water, or the nature of the fish sought to be caught.

Bait-fishing.

This kind of angling is practised to a great extent in the Thames, the Lea, and other deep and somewhat dull rivers of England. The fish usually sought for in these waters are gudgeon, dace, roach, bream, chub, barbel, tench, carp, perch, and pike: all are sometimes taken by fly; but a bait of worms, gentles, roe, or some other material, is commonly employed. The angler in these rivers usually stands on the shore while fishing; but in some instances he fishes from a punt, or small flat-bottomed boat, in which his chief occupation is to sit watching his float, and pulling in his line when a fish appears to be hooked. Among the apparatus of this order of deep-water fishers, a plummet and line is carried, in order to sound the depth of the river, which having ascertained, the angler puts his float upon the line, at that point which will allow the bait to trail slightly on, or just free of the bottom, while the float swims on the surface.

The first thing the bait-fisher has to learn is the art of baiting his hooks. Taking the hook in his right hand, and the bait between his fingers in the left, let him enter the hook at the head of the worm, and carry it through the animal to near the tail, covering the entire hook and its tying. The worm should be broken or mangled as little as possible; and the more lifelike it appears, the greater the probability of its proving an effectual lure. There must not, however, be too much spare worm left dangling from the hook, otherwise the fish will keep nibbling it away without biting at the bait bodily, and taking it into its mouth, the thing which the angler desires.

In throwing the line with bait, take care not to splash the water, but throw somewhat horizontally forward, so as to let the bait fall gently on the surface, and sink slowly in the water to the required depth. After sinking, the rod and line should be very slowly moved in a direction against the stream, or in some other way to give motion to the bait, which the fish perceiving to glide through the water, will hasten to seize upon. As fishes, however, are always on the outlook for floating garbage, one-half the dragging and twittering which bait-fishers generally employ is altogether useless, often positively hurtful, as scaring rather than alluring the objects of their capture.

Occasionally the angler will *feel* a nibble, but he must not be in a hurry to *strike*—that is, to draw the fish from the water. Perhaps it is no more than a nibble, and it is well to allow the fish time to get the hook in his mouth. If drawn too quickly, you may actually pull away the hook after it is half-gulped. Experience and dexterity are required in this ticklish part of the craft. As a general rule, do not strike till the line has been distinctly tugged; then strike by a slow side-motion at first, then a more quick jerk, so as to cause the hook to catch in the jaws of the animal. Supposing the fish to be hooked, do not draw it violently out of the water, as if in a transport of delight, but wind up part of your loose line if necessary, and holding up your rod, retire gradually backward, by which the fish may be landed on the shore. A good angler does not lay aside his rod to take a fish from the hook, unless it be of great size, requiring two hands; if small, hold the rod in the right hand while you catch the fish with the left; unhook it without mangling, place it in the basket, put on a new bait, and once more proceed to your sport.

The *gudgeon*, a fine large fish of the trout shape, affords a favourite amusement to anglers in the Lea, a river near London, and also in the Thames. Blaine thus speaks of this branch of angling: 'Fishing for gudgeons in the Thames is usually practised by means of a punt, which is fixed across the stream part of the river just above a tolerably sharp *scower*, running over a fine gravelly bottom, free from weeds, at depths varying from five to eight or ten feet. As the eddy is greater generally, and the water deeper in these scowers than in those of the Lea, so the tackle used is commonly somewhat stronger, and a fine gut-line is more frequently met with there than one of single hair. Fine tackle, however, in a good hand, is to be always preferred; and we have seen many hundred dozens of gudgeons taken in the sharpest currents of this river also with a single hair only for the two bottom links. Punt-fishing for gudgeon in the Thames is a delightful amusement, particularly to the luxurious angler who is not inclined to take much trouble. The scenery, the quietude, and safety from interruption, the cleanliness of the practice, where the bait is put on the hook by the attendant fisherman, and where even the prize it gains is removed by the same hand, all tend to make it epicurean in the extreme. But the thorough-bred fisher is soon tired with it after this method, for the very reason that there is actually too much luxury in it to constitute true sporting, which must of necessity present some labour to keep up the attention, and some difficulty to enhance the value of the prey. In the Thames, so many as fifty dozen of gudgeons have been taken in a day; but in the Lea seldom half that number are caught. Yet the Lea angler has the best scope for his sport, for he can commence it in March; whereas in all that part of the Thames within the liberties of the city of London, it must not be attempted until the beginning of June, at which time the gudgeons have spawned, and continue for some time afterwards inferior in point of their gastronomic worth. Gudgeon-fishing seems to have varied little from the ancient practice; and the angler who has aught of the antiquary about him, will be amused probably at the close parallel between the present method and the gudgeon-fishing of early times, as it is described by John Davers or John Dennys, Esq., for it is a disputed point to which of these worthies the *Secrets of Angling*, in which it is contained, owes its birth. Walton ascribes it to Davers, and gives the name at full length in the fifth edition of the *Complete Angler*:

"Loe, in a little boat where one doth stand,
That to a willow bough the while is tied,
And with a pole doth stir and raise the sand,
Whereat the gentle streame doth softly slide;
And then with slender line and rod in hand,
The eager bite not long he doth abide.
Well loaded is his line, his hooke but small,
A good big cork to bear the stream with all.

His bait the least red worme that may be found,
And at the bottome it doth alwayes lie;
Whereat the greedy gudgion bites so sound,
That hooke and all he swalloweth by and by.
See how he strikes, and pulls them up as round
As if new store the place did still supply;
And when the bit doth die, or bad doth prove,
Then to another place he doth remove."'

The *roach* is a thick fish, deep from the back to the belly; it inhabits the bottom of deep rivers or lakes, and is usually reckoned so incautious and silly as to be called the water-sheep; nevertheless, it is not taken without some degree of skill. It is angled for by means of bait sunk to within a few inches of the bottom. The fish may be attracted by throwing in some crumbs of bread. It is caught in the Thames some time after the end of August. The baits used are gentles, red paste, and boiled malt or wheat; one grain of the latter is sufficient. Great attention is required to strike quick when the bait is taken. Dace and tench are angled for much in the same manner. Carp is angled for

in stagnant waters from February to September, and the baits are worms, larvæ, grain, and pastes. The perch also inhabits dull waters, and is a short unshapely fish, soft in the flesh, and seldom worth cooking. It is so eager to bite, that little skill is required in pulling out a whole fry; the baits employed for it are worms, insects, and minnows.

Pike-fishing.

The pike is a voracious fish, and may very appropriately be termed the fresh-water shark; it does not confine itself to feed on worms, insects, fish, and frogs, but will devour water-rats and young ducks, and attack much larger animals. We are told, also, that on one occasion a snipe was found in the stomach of this voracious tyrant. All small fish are terrified at the approach of this marauder, which, if permitted, would soon clear a pond of all its finny tribes. 'Pike,' says Daniel, 'love a still, shady, and unfrequented water, with a sandy, clayey, or chalky bottom—arriving at a larger size in pools than rivers—and from May to the beginning of October they usually place themselves amongst or near flags, bulrushes, and water-docks, and particularly under the *Ranunculus aquaticus* when in flower, and which floats on the surface. They will sometimes be found in the termination of sharp currents. From March to the end of May, they resort to back waters that have direct communication with the main stream; as winter approaches, they retire into the deeps, under clay-banks, bushes impending over the water, stumps and roots of trees, piles of bridges and floodgates. They spawn in March or April, according to the coldness or warmth of the weather, quitting the rivers for the creeks and ditches communicating with them, and there dropping their ova in the grass and reeds; in ponds, they choose the weeds upon the shallows for depositing it; ducks and other wild-fowl eagerly devour the spawn, and by them it is transported to other waters. The appearance of the pike in ponds where none were ever put, has been deemed as extraordinary as its asserted longevity; it is, however, easily accounted for upon the well-known principles of the generation of fishes. If a heron has devoured their ova, and afterwards ejected them while feeding in one of these ponds, it is highly probable that they may be produced from this original, in the same way as the seeds of plants are known to be disseminated.

'Pike are in season from May to February—the female fish are to be preferred—are bold biters, afford the angler good sport, and may be fished for all the year; but the best months—especially for trolling—are February, before the weeds shoot, and October, when they have rotted down; the latter is to be preferred, as the pike are fattened by their feed during the summer; and from the lowness of the waters, their harbours are easily discovered.'

The same author thus describes the method of trolling for pike: 'For trolling, the rod should be twelve or fourteen feet long; but a strong top for this fishing, with a ring at the end for the line to run through, may be fitted to a fly or general rod; there should be one ring upon each joint to conduct the line, which is better than a greater number (and these rings must be set on straight, that it may run freely, so that no sudden check after the bait is taken prevent the pike from gorging it). The line should be of silk, with a swivel at the end to receive the armed wire or gimp, and at least thirty yards long, wound upon a winch or reel fixed to the but-end of the rod. Hooks for trolling, called dead gorges, and other sorts for trolling, snap, and trimmer, and fishing-needles, are to be bought at every shop where fishing-tackle is sold. In the choice of the first, let them not be too large, nor their temper injured by the lead on the shanks, nor the points stand too proud; and although usually sold on wire, it is recommended to cut off the wire about an inch from the lead, and with double silk, well waxed, fasten about a foot of good gimp to the wire, with a noose at the other end of the gimp large enough to admit the bait to pass through, to hang it upon the line. The best baits are gudgeons or dace of a middling size. Put the baiting-needle in at the mouth, and out at the middle of the tail, drawing the gimp and hook after it, fixing the point of the hook near the eye of the fish; tie the tail to the gimp, which will not only keep it in a proper position, but prevent the tail from catching against weeds and roots in the water. Thus baited, the hook is to be fastened to the line, and dropped gently in the water near the sides of the river, across the water, or where it is likely pike resort. Keep the bait in constant motion, sometimes letting it sink near the bottom, and gradually raising it. The angler need not make more than two or three trials in a place, for if a pike be there, he will within that time bite if he means to do so. When the bait is taken, if at a depth too great to see, it will easily be ascertained by the line being drawn tight, and by some resistance. Let the pike have what line he chooses; it will be soon known when he has reached his harbour by his not drawing more. Allow from five to ten minutes for his gorging the bait; wind up the line gently until the pike is seen—which he will permit though he has not gorged—should the bait be across his mouth, give more time; but if he has swallowed, manage him with a gentle hand, keeping him, however, from roots and stumps, which he will try to fasten the line upon; in clear water, veer out line until he is sufficiently tired, and a landing-net can be used; but by no means, however apparently exhausted, attempt to lift him out with the rod and line only; for the moment he quits the water, he will open his mouth, and from his own weight, tear the hook from his stomach; and the fish will be lost to the angler, although it must inevitably perish. In trolling, the bait should never be thrown too far: in small rivers, the opposite bank may be fished with ease; and the violence of its fall upon the water, in extensive throws, soon spoils the bait by rubbing off its scales, and alarms the pike instead of enticing him. Pike are to be allured by a large bait, but a small one is more certain to take them. Never suffer weeds to hang upon the hook or bait when recast into the water, and which cannot touch the surface too softly. Always prefer a rough wind, and when the stream is clear, for trolling; pike never bite in white water after rain or freshets. If a pike goes slowly up the stream after taking the bait, it is said to be a signal of a good fish.'

Mr Stoddart's methods of angling for pike here deserve notice: 'In rod-angling for pike, we adopt three methods—employing the gorge-tackle, the swivel-tackle, and the fly. Our gorge-hook is double brazed, and armed upon brass wire. A parr, or small trout inverted, is the usual bait. We insert the wire of our tackle through the fish, bringing the upper end of it out at the tail, and allowing the two barbs of the hook to protrude from its mouth. In angling, we both throw and drop the bait, as the nature of the water demands, moving it slowly towards the surface. When a pike seizes it, there is at first no perceptible tug; one feels as if he heard the shutting of a pair of jaws on the bait; and if you can manage to see your fish, you will observe him holding your trout by the middle, as if crushing the life out of it. Keep a tight line, but do not pull or strike. Too much resistance places your intended victim on his guard; a little, however, sharpens his appetite. After a few seconds, the pike will begin to move towards his den, still grasping your bait betwixt his teeth, and intending to bolt it immediately. Let out line with your hand from the reel; and now he is fixed, and darts off like a tiger, shaking his chain, and with open mouth tossing himself out of the water at thirty yards' distance—the worst is over, and he turns revengefully towards the shore; wind up—ha! he is out again, and again he makes for the shallows; but the monster is exhausted,

and moves heavily; lead him with caution to the edge, lay down your rod, and lift him upon the bank. In order to disengage your hook from the entrails of this formidable fish, the gills should be forced open, and a knife introduced for the purpose, taking care previously to thrust it through the spine-bone of your victim, and so prevent the possibility of your catching a Tartar. Unfasten your hook from the wire before drawing the latter through the mouth of the pike, as otherwise it is again apt to catch among the teeth, from which it may be somewhat difficult to extricate it, without incurring a few scratches.

'Should a fish, after having bitten, abandon your gorge-hook, try him with a running-bait upon swivels, and let this be a fresh trout of a smaller size than your other, and fixed upon a gimp-tackle with the tail downwards, as in minnow-fishing. See that it spins judiciously; and when the pike rises, let him turn with the bait before you strike. River-pike, it may be remarked, seldom play so well as those in lochs. They push generally below the banks instead of striking across, and look out for old stumps upon which to entangle and break your line. One ought, therefore, to make quick sport with such rascals—running them down upon level banks in a twinkling, and before they are able to get under-way.

'The third method of angling for pike is with the fly—a kind of fishing not much in use, but still on some waters very deadly. The pike-fly should be large and gaudy, fabricated of divers feathers and tinsels, to resemble the king-fisher or a huge dragon-fly. Use it in a strong warm wind, upon water from six to two feet deep, and near weeds. You will kill with it fish of various sizes, from ten inches in length and upwards: very heavy ones, however, refuse to take it, on account, probably, of the exertion necessary in order to come to the surface. We have always noticed that the biggest pike are caught during close sultry weather with a ground bait, and at those times when trout refuse food altogether; also at night, with set lines, in the summer months, when they leave the weeds and bulrushes in quest of food.

'Although the pike is often nice and suspicious in places where trout abound, still, when provoked, he becomes bold and unwary, treating your presence as no constraint upon his temper and appetites. He will follow the bait to your very feet, and should it escape him, will retire a yard or two, waiting eagerly for its reappearance. When angry, he erects his fins in a remarkable manner, as the lion doth his mane, or the porcupine his quills; moreover, the pike appears careless of pain, if indeed fishes in general feel it to any great degree. We have actually landed one of these fish, cooped him alive in our creel, and when by some negligence of ours he made his escape into the water, have succeeded a second time in securing him. On another occasion, we remember having a part of our tackle, consisting of a large double gorge-hook dressed upon brass wire, carried off by a pike; and yet, upon renewing it, the aggressor returned to the charge, and was taken. The former hook we discovered gorged by him in such a manner as must, we thought, not only have suffocated any other animal, but done so by the medium of the most exquisite internal agony.

'Great injury has of late years been done by the transference of the pike to many of our best trouting lochs, where a single individual has been known to consume nearly its own weight of fish daily. This was the case on Loch Turit, near Crieff, where the trout, formerly abundant, are now greatly reduced by the hostile and merciless depredations of their natural enemy. The pike at table is reckoned by some a coarse dry fish, and so in general they are; yet to our knowledge, in certain lochs, for instance that of the Lowes in Selkirkshire, they almost rival the turbot, and should be cooked somewhat in a similar manner. They are none the worse for being kept a few days, especially if of any size. A good eating pike ought to weigh at least from five to twelve pounds—the smaller ones being without exception bad.'

Trout-fishing.

The trout is of different species and varieties, as the common trout, the gillaroo or gizzard trout of Ireland, the bull trout, and the salmon trout. The shape is handsome; the flesh firm and sweet, and coloured pink or white, according to species and feeding-ground; and the weight varies from a quarter of a pound to eight or ten pounds. In one or other of its varieties, the trout is a universally known fish in temperate climates; its favourite haunts are clear running rivers; and there, both in England and Scotland, it affords a favourite object of sport to the skilful angler. Sometimes bait is employed, but the fly is more common. In some cases, the bait and fly must be tried alternately in one day, as the fish is capricious, and requires to be tempted in all kinds of ways. The season most favourable for trout-fishing is spring and early summer. Mr Colquhoun, in his interesting work, entitled *The Moor and the Loch*, gives a great deal of information on both loch and river fishing. *Fishing with Bait.*—'Trout,' says Blaine, 'begin to take a bait on or near the ground early in the year, and before March, will readily take most bottom baits all day long in favourable weather; but as the summer advances, it is only very early or very late in the day that they will take a bait near the ground, they being at the intermediate hours more disposed to rise to the surface for winged insects. In March and April, use the worm in the forenoon, and a fly or minnow, according to the state of the water, the rest of the day, in the swiftest and sharpest currents, provided the day be warm and bright, and in the deeps early and late; but if the water be discoloured, or very thick, try the gravelly shallows near the sides and tails of streams with a worm only, to run on the bottom with one large shot a foot at least from it. When there is a small *fresh*, or the water is clearing off, and is of a dark-brownish colour, first use the worm, which should be a well-scoured brandling, cast in as a fly at the head of the stream, and move it gently towards you, still letting it go down with the current, so as to keep it a little under water: the line should be rather short, with no lead upon it, and the hook fine; then try the minnow, and as the water clears, the artificial flies should be tried. In fishing for trout with the worm, use running-tackle, and employ a strong line, but let its strength consist in the excellence of its material rather than its bulk, to which end the hook should be small, the gut fine, the shotting fine also, and let the whippings be well concealed, for in bright water trout are singularly wary and suspicious.

A short line and quick striking are recommended by Mr Stoddart, who says the line 'ought always to be kept at its full stretch, and moved in a half-circle with the angler. It requires some degree of perception to know the exact instant when the fish first seizes your bait; it does so with such softness, and with no likeness of a tug, as one is apt to imagine; nay, it merely closes its jaws upon the hook, as a gaping oyster would do upon one's finger. Then is your opportunity for striking; if you neglect it, you allow the trout its more leisurely process of nibbling, and its chances of escape. In striking with the short line, do it sharply, and never against the current, but rather with it, in a diagonal direction, and not too high. The reason of this advice is obvious, for all fish feed with their heads pointing up the stream—kindly giving you the choice of pulling the hook into or out of their mouths; the latter of which purposes you accomplish, to a dead certainty, by striking against the current. This whip-jack manner of bait-fishing is very deadly with an experienced hand. The long-line anglers make nothing of their method comparatively; and yet, among clear waters, and where fish are few, or bite shyly,

patience and a long line will carry the day. Remarkably fine gut ought to be used by all ground-anglers, whatever be the practice. Trout are a suspicious, distrustful set, and three in general slink off for one that nibbles; terrified, no doubt, by those singular accompaniments of your worm, a line and hook.

'To all bait-fishers, Scotland affords excellent sport; her rivers run so strongly, and are maintained by so many sources in the shape of mountain burns. These romantic streamlets abound in trout; every stone shelters its inhabitant, and the meanest pool is peopled with numbers. Burn-fish, however, are generally of a small size; they seldom exceed a pound in weight, except in the spawning season, when larger ones ascend from broader streams or lochs at a distance. Still, the taking of them is a pleasant pastime, especially when they bite eagerly at your worm, as they do during rain and in discoloured water. At such times, you have only to drop your bait without art, and the fish will manage its own ruin.'

The same enthusiastic brother of the rod next proceeds to treat of minnow-fishing, which he says is by far the pleasantest mode of capturing trout, next to angling with the fly. 'If you wish to engage in this pleasant sport, provide your minnows by means of a small drag-net or hook. Fish in rapid streams, also in deep discoloured pools, and during a smart curl. Manage the minnow as you would your fly, throwing it down and across as far as you are able; bring it towards you about six inches or more below the surface, spinning rapidly by the aid of several swivels. When a fish rises, give him time before you strike; let him turn and gorge the bait, then strike sharply, and he is yours.

'Trout seize a minnow by the middle or near the head, and you generally hook them on the upper hooks. In rivers where numbers of minnows are found, you must angle with the very smallest, not above two inches in length, and use a proportionate tackle. The trout in such waters love delicate tidbits, and are absurdly nice in their feeding. Artificial minnows are frequently used by anglers, and with considerable success.'

'Trolling with parr for large trout,' he continues, 'is a glorious pastime, especially on a Highland loch, circled with mountain scenery—the craft of nature by incantation wrought, when the morning-stars sang together. It needs intellect to enjoy it well, and a poet's heart to know its luxury. Take with you some choice and idle spirit, a rower he must be, that can manage your airy shallop as the winds do a weathercock—can chant a ballad of yore, of ladye and chieftain, and pranksome elf and kelpie wild—can speak to the echoes and to yourself, cheering you with wit and wisdom, and admiring your science and skill, and the gorgeous fish you are playing, twenty fathom off, with a strong and steady hand, your heart "high fluttering the while, like woman's when she loves."

'Tackle for trolling should be dressed upon tried gimp. Bait as you do with a minnow: use a strong rod, heavy lead, and a long line of oiled cord wound upon an easy reel. Choose a sunny day, with a stiffish breeze, and troll near, but not amongst the weediest parts of the loch. Plant yourself at the boat stern, and get rowed gently at the rate of three miles an hour, letting out from twenty to thirty yards of line betwixt you and your bait. Trout from six to nine pounds' weight cause the best sport when hooked; a larger one seldom leaps or makes any violent exertion to escape; he swims sullenly, and at ease, regarding the angler with a sort of sovereign contempt. You must row after him, and turn him if you can before he gets among weeds; never slack your line for an instant, and look well about you. Land as soon as you are able, and play him from the shore. Your companion will assist you at the death.

'So much for the different kinds of bait-fishing practised in Scotland. We esteem it folly to talk of the less popular baits used by the *virtuosi*—of frogs, grubs, and leeches, water-rats, and mice—all of which animals trout will devour. It might be asked, may fish not be taken with anything? They have been known to swallow money, rings, and many other glittering marvels; nevertheless they seem to have no pleasure in snapping at the bait of the unskilful angler, and refuse to die under his hands.' Parr-tail, and a small fish called in Scotland the beardie, make excellent spinning-bait, and are frequently used with deadly effect.

Fishing with Fly.—This, after all, is the true angling, all other efforts at taking fish being either somewhat childish or murderous. A long flexible rod, fine lines, and appropriate flies, are the necessary equipment; and the best time for making the attempt is on a dark lowering day, at anyrate not in bright sunshine. If the moon has shone brightly the previous night, it will have prevented the trouts from feeding freely, and they will accordingly bite more readily when tempted with the artificial fly. Great skill and nicety are required in throwing the fly-line. Mr Stoddart gives the following directions how to proceed:

'Your rod and tackle being ready, the wind in your favour down the river, draw out with your left hand a few yards of line from your reel, dip the top of your rod in the water, and with a rapid jerk you will lengthen as you wish that part you intend for throwing. A thirteen-foot wand will cast from six to seven fathoms of line. With a large double-handed rod you may manage a much greater length. Always, if you can, angle from a distance. Trout see you when you least imagine, and skulk off without your notice. Noise they care little about; you may talk and stamp like a madman without frightening them, but give them a glimpse of your person, and they won't stay to take another. Some ichthyologists attribute to them an acute sense of hearing: this we are disposed to question; for how happens it that the most obstreperous rattling of stones, when wading, causes no alarm, although conveyed to them through the medium of water, a good conductor of sounds? We remember angling one still night by St Mary's Loch, when our movements were heard distinctly by some shepherds at the distance of a mile, and yet the fish rose eagerly at our very feet, following our fly to the shallowest parts of the margin—a fact which, if it does not prove obtusity of hearing on the part of the fish, at anyrate renders it a matter of little consequence to the angler.

'It requires some art to throw a long line. The beginner should commence with a short one, and without flies, lengthening it gradually as he improves. The best method of casting is to bring the rod slowly over the right or left shoulder, and with a turn of the wrist, make the line circle behind you, then, after a pause, fetch it forward again in the same manner, and your flies will descend softly upon the water. All jerks are apt to whip off your hooks or crack your gut. A fly-fisher may use two, three, or four flies on his casts, according to pleasure. When angling with small hooks, we adopt the medium number. Large ones ought to be fished with in pairs and well separated. In throwing the cast, the lowermost or trail-fly should be made to alight foremost; its fall ought to be almost imperceptible; it should come down on the water like a gossamer, followed by the droppers. The moment a fly touches the surface, it is ten times more apt to raise a fish than during the act of drawing it along. At no time are we stanch advocates for the system of leading our hooks either against or across a stream; our method is rather to shake them over it for a moment, and then repeat the throw. A trout will discover your fly at the distance of several yards, if feeding, and will dart at it like lightning. Always, if you can, fish with the wind, and do not concern yourself, as some do, from what quarter it comes. In spring, no doubt, a south-west breeze is preferable to all others; yet we have seen even easterly winds not the worst on many waters, especially during

summer months, when the natural fly is apt to become over-plenty.

'Trout will sometimes take in the most unlikely weathers, so that the angler should not despair at any time. Hunger causes them to feed at least once in the twenty-four hours, and generally much oftener. If the wind blows down the river, commence at the pool head, and fish every inch of good water; you may pass over the very rough and very shallow parts, also those which are absolutely dead calm and clear, unless you see fish rising in them, when, should your tackle be light, there is no harm in taking a throw or two. Dead water, however, when rippled or discoloured, may be angled in with great success. When you raise a good trout, strike slowly, or hardly at all; only continue the motion of your hand without slacking it; the fish, if large, will hook itself. Small trout and parr may be whipped in with rapidity: it is folly to play or use ceremony with such trifles. Should the fish miss your fly altogether, give him another chance, and a third, if that will not do; a touch of your barb, however, will sharpen his wits, so as to prevent him from again rising. He prefers flies without stings. When you hook a trout, if you can, turn his head with the stream, and take him rapidly down. Thus you will exhaust him in the shortest time; whereas, by hauling against the current, you allow him to swim freely in his natural direction, and also exert three times more strength upon your tackle than is really needful. A good-sized fish, handled in this foolish manner, can never be taken; it is impossible to tire him out, and the strongest line will give way to his resistance. When your victim is exhausted, draw him gently ashore upon the nearest channel or most level part of the margin. He will come in sideways, and generally lie motionless for a few seconds, during which time you will be able to run forward and seize him. Beware of catching hold of your line until he is properly banked. Many a famous trout have we seen lost by this inadvertence on the part of anglers, who think so to save time and labour. One should remember how the spring of the rod is thus removed, and how there remains no proper curb to the strength of the fish, which easily breaks a single gut, or tears itself from a sharp hook, and wishes the astonished angler better sport further on.'

The practice of double-rod fly-fishing for trout or for salmon, is a murderous kind of sport, and should be prohibited by law. A line stretched between two rods, and hung with flies, is taken down the stream by two individuals on its opposite sides, so that every part of the water is gone over, and every feeding trout raised. By this plan, large numbers are caught, but many also are wounded, and escape, to pine away for months at the bottom, unable either to feed or spawn.

Salmon-fishing.

This may be described as a gigantic trout-fishing, the principle of alluring and capturing being the same, but all the tackle requiring to be stronger, and a greater degree of physical power being necessarily called into operation. The salmon has a peculiar habit, very likely to upset the calculations of beginners: it consists of the ugly practice of running off at a violent speed as soon as he feels himself hooked, darting up the stream, throwing himself several times out of the water, and generally in the end hastening into some sheltered haunt under the banks where he expects to be safe. Great tact is necessary on these occasions, first to give line, and then to keep him from burying himself in these unapproachable nooks.

With respect to the minutiæ of the art, both in throwing and striking, the recommendations of Mr Younger of St Boswell's are well worthy of attention. 'I recommend a beginner,' says he, 'to practise throwing the line on a broad smooth pool, where he can see that it is delivered out properly, and falls lightly, without splashing. In such a case, the practitioner will perceive something which he cannot easily account for—and that is, that after he has even attained a great degree of perfection in the art, he will not be able to distinguish how it happens that in one throw his long line will proceed direct out, his fly alighting first on the water; in another throw the middle of his line will fall first, while the further part, still obedient to the general impulse, will proceed out the full length, the fly falling the last on the surface. This last throw is not so good as the former; for this reason, that the main current having caught the middle of his line first, carries it too quickly down, leaving the fly lagging, to form an awkward curve, as, before it comes over above the fish, the fly should lie on the water, so as to have the appearance of plying at an angle against the current. And the angler should so manage his rod, that while he lets his line float round at its full length, yet to cause his fly to come as slowly as possible over the main spot. In this case the salmon will sometimes rise at once, rather before you expect him, but more generally will follow the fly to the eddy, or edge of the deep, where, if on examination he feel disposed to seize the hook, he has it before you perceive a head, fin, or tail above the surface. Indeed, before you perceive the web of his tail, he generally has the hook in his jaw a foot below water, as in descending he goes, like other divers, head-foremost.'

Having managed to place the fly over the desired spot, our authority continues: 'He will make no perceptible motion to keep his fly on the surface (except on a sluggish pool), but let it sink a little, depending on feeling rather than on sight; and though apparently keeping no pull on his line, yet all the while able to detect the touch of a minnow. On a *boil*, or other appearance of a fish, he pulls up his line, not twitchingly but actively, steps a yard or two back, rests a minute to let the fish resume his lair and attention, and perhaps feels inclined to alter his fly, before he annoy and disgust or alarm his fish, to a shade darker or a size smaller, when he will most probably come up and seize it in earnest. Should he not rise again, or rise and pass it thrice, leave him quietly alone for the present, and return to try him some time afterwards. On taking the fly, the fish means to return with it to his precise select *spot* of lair, on rock, stone, or gravel, at the bottom; and the fine angler, holding him gently, often in the first instance allows him to do so, but soon, too surely feeling his awkward predicament, he bolts off, "indignant of the guile." Then is the time when the fisher is attentive. With the but-end of his rod resting on his thigh or groin, he keeps the top nearly erect, never allowing it to fall below the proper angle of forty-five degrees, as relative to the situation of the fish, as in this position the elasticity of the rod never allows the line to slacken in the least degree for a single instant, however the fish may shake, flounce, jerk, or plunge. With two or three fingers and the thumb of his left hand, the angler holds his rod while the wheel-line runs out, regulated by the first or first and second fingers, relieved or assisted, as occasion may suggest, by the right hand, when it can be spared from its necessary occupation of rolling up the wheel-line, as the fish settles a little or returns inwards. In this manner the fish is allowed to run right out, up, down, or across, as he may choose. But if in an outright dash of thirty or fifty yards aslant, ending in an outward-bound fling above water, the inexperienced angler should feel flustered, which he is very likely to do, and by some involuntary twitch of the running line let the top of his rod be pulled down to a level with his own head, then the tug of the last plunge will assuredly break his hook or line, or tear the hook from the mouth of the fish; or, what is as bad, a sudden jerk or turn of the fish will give the line a momentary slackening, when the hook's hold, already so strained as to have widened its incision, will fall out, and your fish is gone for ever.'

Now is the critical moment for the salmon-fisher, who must keep up his rod and give line. 'The fish will then,'

continues John, 'allow himself to be led at ease to the angler's side of the river, like a bridegroom to the altar, when, on finding the water shallowing, he will again make another desperate effort, probably a new dash into the middle current; but too much exhausted to resist the still continued pull upon him, he will soon again fall into the shallow, where, on a sight of his enemy, he is again alarmed into a new effort, and again exhausted by turning his outward-bound head down with the water, again and again, and again, as if the parties were in the amusement of forming circles, until his own last efforts to keep swimming are made subservient to the cautious angler in moving him by degrees into the shallow, where, half dry, he must, like all the strong, at last yield to his fate, and fall panting on his side, while the line rolled up to within rod-length, which is to be held with its top landwards, without slackening, and the fisher seizing him with the forefinger and thumb of his right hand across by the root of the tail—which is by far the surest method of seizure—lifts, or rather slides him out head-foremost over gravel and grass, and in mercy fells him with a blow on the back of the neck.

'After going through this process with a twenty-two pounder—and the process would be the same with a forty-four—the writer can aver, that he does not conceive that from the moment he has hooked such until he was laid on the grass, he ever for an instant had three ounces of more or less pull on the fish; for in all circumstances of run, regularity of pull is the sure test of true skill and final success. Indeed, I have seen many a fine fish laid on the dry gravel when the hold of the hook in the lip of his mouth was so slight as to be smaller than the steel of the hook—so much for equal pull and cautious management in the run. And, in short, a man is never a master-angler so long as a desire to have his hooked fish to land excites in his feelings the least agitation, as the matter should be managed with that cool philosophical ease of mind which is alike above the paltry calculations of loss and gain and the common ridicule, which often tends to stir up a degree of childish fretfulness. This perfect nonchalance is absolutely necessary to first-rate excellence and ultimate success.' Though it may be contrary to the usually established custom, and appear cruel to a sensitive mind, still we have been told that it is a mistake to kill either salmon or trout, as they are by that means the more apt to become soft and flabby in the flesh.

Leistering is the name usually given to a murderous kind of sport pursued by salmon-fishers in Scotland. Armed with *leisters*, or spears with three-barbed prongs, a set of fishers proceed to the river's bank, and there attract the fish by the glare of torches held over the water by members of the party. When a salmon is discovered, one selects it as his prey, and by a cool but rapid blow transfixes it with his spear. In many cases, the fish cannot be secured or landed without plunging into the water; but this usually forms no obstacle, and several men may be seen floundering in the depths of the stream while shouts and confusion prevail among the spectators on the banks. Sir Walter Scott, in his novel of *Guy Mannering*, has presented a vivid picture of this species of sport, which is still pursued on the Tweed and its tributaries, but mostly by parties of rude marauders who are regardless of law, and kill vast numbers of fish during 'close time,' or when the rivers are legally shut. As the law at present stands, all salmon-fisheries north of the Tweed close on the 14th of September; Tweed net-fishing on the 1st of October; and Tweed rod-fishing on the 14th of October. The fisheries north of the Tweed open on the 1st of February; and those of the Tweed, both for rod and net, on the 1st of March. (See FISHERIES.)

The Parr.

The parr is a small fish, which is found in great abundance in almost all rivers which are clear, and have a free communication with the sea. It varies in size, of course, according to its age, but seldom reaches a greater length than six inches, and is usually found below that magnitude. It is silvery in appearance, and marked by peculiar bluish bars or marks along the body; while a more nicely forked tail, and one regular row of scarlet spots along the sides in place of two or three, aid further in distinguishing the parr from the trout, the fish which it most resembles.

Of the actual character of the parr, whether it is an independent species or the fry of salmon, there has been a long-continued controversy. Many naturalists were inclined to hold it as a kind of mule—a creature betwixt the trout and salmon breeds. The dispute, however, may be said to have been terminated by Mr Shaw of Drumlanrig, whose lengthened and ably conducted experiments have established the parr to be the natural produce or fry of the salmon. In a memoir communicated to the Royal Society of Edinburgh, Mr Shaw mentions that his first experiment on the subject consisted in the removal of a number of parrs from their native stream to a pond, when he found that all of them assumed the perfect appearance of *salmon fry* or *smolts*, at the end of periods of time proportioned to their bulk when placed in the pond. He also satisfied himself that the change from the state of parr to that of smolt, which is marked by the appearance of a covering of silvery scales over the blue bars, always takes place at the age of *two years;* and that then, for the first time, the metamorphosed fry take their downward departure for the sea.

But it was objected to these experiments, that Mr Shaw might have mistaken young salmon for parrs in the first instance, so rendering his conclusions of no weight. To settle all disputes, he began his experiments with the *ova* or *eggs* of the salmon, first constructing ponds for their reception. These ponds, three in number, he protected by falls, pipes, and gratings, in such a way as to seclude them in a perfect manner from all interference on the part of any other fishes whatsoever. Having provided a proper net, Mr Shaw was successful in capturing a pair of adult salmon, male and female, while engaged in depositing their spawn. By expressing a portion of the ova from the female, and of the milt from her companion, he had it in his power to transfer fertilised ova to his ponds on the 27th of January 1837. 'On the 21st of March, fifty-four days afterwards, the embryo fish were visible to the naked eye. On the 7th of May, they had burst the envelope, and were to be found among the shingle of the stream. It is this brood which I have now had an opportunity of watching continuously for a length of time.

'At the age of four months (7th September), the characteristic marks of the *parr* were clearly developed. Two months later (six months old, 7th November), an accession both of size and strength was apparent; and on comparing the pond specimens with those of the river, no marked difference was perceptible. The average length at this time was three inches.' Mr Shaw goes on (in a paper read to the Royal Society) to describe a number of specimens, at different ages, of which we give four.

'Number six is a specimen from pond number one, of the age of nine months, taken in the middle of February 1838. It exhibits little or no particular accession of size or condition to that of number five, but may serve to shew the general appearance of the several broods of the young salmon in my possession at the age of nine months.

'Number seven is a specimen twelve months old, taken from pond number one, on the 10th May 1838. It is much improved in condition, as well as in external appearance, in comparison to that taken in February, and has exchanged its dusky autumnal and winter coating for that which may be called its summer dress. It measures about three and three-quarter inches in

length, and is denominated, along with those of a corresponding age and size in the river, the *May Parr*. Immediately after the migration of the two-year-old parr—which the latter always effect about the beginning of May, under the name of salmon-fry—there is no other parr, besides such as have been recently hatched, to be found in the river, save those which correspond with this specimen, which is the *Pink* of the river Hodder alluded to by Mr Yarrell. As the summer advances, they increase in size, and are actually the little fish which afford the angler in salmon-rivers so much light amusement with the rod during the months of August, September, and October. They remain over the second winter in the river, during which period the males shed their milt, and are found continuing their kind along with the female adult salmon, although still bearing all the external markings of the parr, as I shall afterwards more particularly mention.

'Number eight is a specimen eighteen months old, taken from pond number one, on the 14th November 1838. It measures six inches in length, and has now attained that stage when all the external characteristic markings of the parr are strikingly developed, and, in point of health and condition, cannot be exceeded by any taken from the river. All the males, at the age of eighteen months, of the several broods in my possession, last autumn (1838) attained a most important corroborative stage—namely, that of shewing a breeding state, by having matured the milt, which could be made to flow freely from their bodies by the slightest pressure of the hand. The females of the same broods, however, although in equal health and condition, did not exhibit a corresponding appearance in regard to the maturing of roe. The male and female parrs in the river, of a similar age, are found respectively in precisely a corresponding state, which may surely be admitted as important evidence in support of the fact, that all these individuals are, in truth, specifically the same.

'Number nine is a specimen two years old, taken from pond number one on the 20th May 1839, *after having assumed the migratory dress*. The commencement of the change, which was perfected by the whole of the broods about the same time, was first observable about the middle of the previous April, by the caudal, pectoral, and dorsal fins assuming a dusky margin, while at the same time the whole of the fish exhibited symptoms of a silvery exterior, as well as an increased elegance of form. The specimen in question, so recently a parr, exhibits a very perfect example of the salmon fry or smolt.'*

Subsequent observation and experiment have abundantly confirmed Mr Shaw's conclusions as to the parr being the young of the salmon, and that it becomes transformed into the salmon fry or smolt. But it is still an unsettled point how long the parr state continues. Mr Shaw admits that individuals assume the migratory or smolt dress at the age of twelve months. His opponents maintain that this is the rule, and that cases in which the transformation does not take place till the beginning of the third year are exceptional, the natural development being interfered with in some way. The state of confinement in which Mr Shaw's broods were kept, is thought sufficient to account for their slow development. Experiments on a large scale have since been carried on at Stormontfield, near Perth, with a view to determine this question. In the beginning of June 1855, a brood then fourteen months old, many of which had quite recently undergone a transformation in appearance, were allowed their liberty; when about half availed themselves of it, the rest remaining in the pond. Some thousand of those that took to the river were marked, and several of these were caught in the river in July and August of the same year, having migrated to the sea, and returned as grilse of from three to seven pound. The biennial period, then, is not so absolute as Mr Shaw would make it; still the chief authorities seem to think it much nearer the truth than the annual.

* One or two of each of the three broods assumed the migratory or smolt dress at the age of twelve months.

The smolt, on entering the sea, grows with surprising rapidity; according to Mr Young, its stay seldom exceeds two or three months, and during that time it expands from a few ounces to as many pounds. But on this point, too, there are conflicting opinions, some holding that the smolt that enters the sea one summer, does not appear in the river as a grilse till the summer following.

An important point in the natural history of the salmon is the tendency to return to the river in which they were bred. It is no doubt carrying the idea too far to maintain that they always do so; and the cause, instead of the unerring instinct to which it has been ascribed, is perhaps to be found simply in the distance between the mouths of rivers. In the main, however, it may be held as a fact, and one that affords inducement to protect the fish in the spawning season, and also to increase their numbers by artificial breeding.

In Mr Young's experiments in the river Shin, he found that grilse caught in spring while descending to the sea after spawning, and marked, returned within three or four months, as full-formed salmon, having increased from four pounds to nine or fourteen pounds in weight. The adult fish, after spawning, are called *kelts;* the male fish is sometimes also called a *kipper;* and the female, a *shedder* or *baggit*.

Of late years, attention has been turned to the importance of stocking rivers with fish artificially, by means of breeding-ponds, where the eggs or spawn and the young fish are protected for a time from the many accidents and enemies to which they are exposed in the earlier stages. New and profitable kinds of fish are also introduced into rivers in this way. In France and Germany, the practice is said to be attended with marked success, and is coming to be looked upon as a new branch of national economy, under the name of *pisciculture*. Efforts of the same kind have been made in Scotland, as at Stormontfield, near Perth; though in the case of a migratory fish like the salmon, the effect is extremely difficult to ascertain.

Mr Boyd has recommended the propriety of securing a few thousands of the fry, just as they are about to assume their migratory dress, and transmitting them to the rivers of Australia and Tasmania. By this means, the inhabitants of those countries would be supplied with this valuable fish.

FISHPONDS.

Artificial ponds for the rearing of fish and supplying them when wanted for the table, were common in ancient times. The luxurious Romans possessed such preserves, and we learn that one belonging to Lucullus sold after his decease for upwards of £24,000. Comparatively little has been done in modern times in the way of establishing artificial ponds, and those which exist are chiefly to be found in noblemen's preserves. Yet artificial fishponds may, with little or no trouble, be made to yield a large and regular supply of fish, and may be constructed at a most insignificant expense in any piece of low-lying waste ground intersected by a rivulet of pure water.

The fish most suitable for ponds are trout, carp, dace, roach, bream, tench, perch, and minnows. Eels also thrive in ponds; and what has frequently been a matter of surprise, these animals sometimes find their way to ponds of their own accord, without actual transfer. It is extremely probable that the spawn or young of eels and other fish is gobbled up and vented by birds in appropriate localities; there is at least no other rational means of accounting for the spontaneous stocking of remote fishponds and lakes.

The size of a pond may be from one to twenty acres; but a piece of water of from two to three acres is

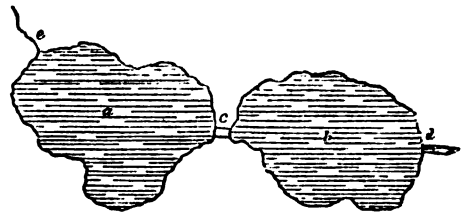
considered the most convenient dimensions. Of whatever size, the pond must not be overstocked, and it must not be left too long unfished. Fishponds, to be on the most effective scale, should be in a series of two or three, the water running from the one to the other. This will allow means for periodical cleaning, if required, and for having a choice of fish. Some remarks of Daniel may here be introduced:—'In ponds so situated as to have communication with each other, never put into the upper of them either a pike, a bream, or a roach; the spawn will get through the gratings, and by that means all the lower ponds will unexpectedly swarm with them. The pike will destroy the fry of the carp and tench, and the two latter will consume all the food which should be the subsistence of both parents and progeny. Pike, bream, and roach should therefore on no account be ever put into the first or highest of a succession of ponds.' He continues: 'Some have recommended, in raising carp, to have three ponds: one wherein the fish are to spawn—which is mostly from May to July—and in which they should continue during the summer and ensuing winter. A second for the convenience of nursing up the young fry, into which they should be put at the end of March, or early in April following, choosing a calm but not sunny day for their removal, and being careful to prevent their being destroyed when coming to the sides of their new habitation. In this pond they may remain two years, and become four, five, or six inches long. The third or main pond is for the reception of those that are so grown as to measure a foot or more in length, including their heads and tails.'

The proportions advised for the stocking these different ponds are—for the first sort, per acre, 'three or four male, and six or eight female carps; those of five, six, or seven years old, in good health, with full scale, and fine full eyes and a long body, without any blemish or wound,' are to be preferred. The pond must be previously cleaned of all sorts of voracious fishes and other animals, as 'perch, pike, eels, and trout; the water-beetle, and also the frogs; the newts or lizards;' have a warm and open exposure with soft water, and all kinds of water-fowl kept from it. For the nursing-pond, a thousand or twelve hundred carp may be not more than sufficient for an acre; and for the main pond, one to every square of fifteen feet is the allowed space, as their growth depends greatly on the room they enjoy and the quantity of food.' As to tench, which are not generally held in the estimation they deserve, Mr Yarrell recommends that large and fine fish be chosen as breeders, as being the most certain mode of obtaining sizeable fish for table in the shortest space of time. Two males to one female, or not less than three to two, should be the proportion of the sexes; and from the pond, which is found by experiment favourable for breeding, the small fish should be in part withdrawn from time to time, and deposited elsewhere, to afford more accommodation for all.

Our friend Mr Stoddart likewise treats of fishponds, but mainly in reference to Scotland, where the fish must be of the hardier kinds—perch, pike, and trout. In either case, the transfer of the fish to the ponds may be made with little difficulty. On being caught with a hoop-net, place them in large jars of water, and cart them to their new habitation; if this be inconvenient, they may be carried in wet moss or straw. All fish bear carriage best in winter, and better during the night than during the day.

'Ponds intended solely for perch do not require to be made large; they should slope gradually down towards the middle from a depth of six inches to one of five or six feet. Water-weeds ought not to be greatly encouraged. A series or chain of small basins, at different elevations, is preferable to a single large reservoir for this fish. These basins should be connected by a sluice and floodgate, so that one may be readily emptied into another for the mutual convenience of cleaning and repairing. Also the uppermost ought to be shallower than those below, and more exposed to the sun, so as to serve for a nursery and breeding-pond. Bream live well with perch in a warm situation; they are not, however, obtained readily in Scotland. Perch-ponds should be let off and paved with channel stones every four or five years; many allow them to remain fallow for some months, and others sow them with grass and oats—a conceit laboriously encouraged by theoretical writers of bygone days.'

The following engraving represents a pair of perch-ponds: *a* is the upper or breeding pond; *b*, the lower

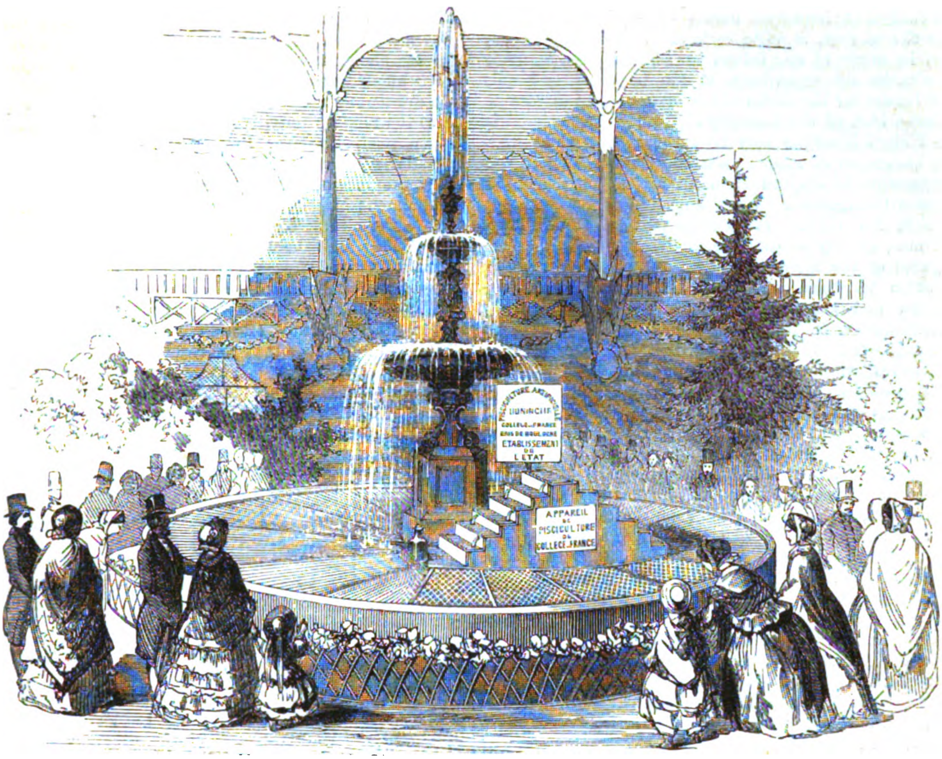


pond; *c*, a covered sluice with movable gratings; *d*, the sluice with outlet; and *e*, the small feeder.

'The pike-pond,' proceeds our authority, 'if for breeding and fattening to some extent, ought to be large, covering from eight to twenty acres; its mean depth six or seven feet. One end, however, should be much shallower, and sown with bulrushes or other water-plants. Previous to stocking it with this fish, a sub-stock of perch or trout should by all means be introduced; otherwise, without a great supply of such sustenance, pike will not only become thin and ill-tasted, but quarrel and devour each other. To facilitate a steady supply of perch, small tanks should be constructed alongside of the leading preserve, with connecting sluices and flood-gates, so as to expel, when necessary, a shoal of live food.'

Our author next treats of trout-ponds: 'Choose from six to twenty acres, less or more of an oval shape, but indented with small bays. Cast a long trench through the middle, from head to foot, noticing that you can readily divert along it the stream just mentioned, which stream is intended as a spawning-place, seeing that trout never shed their roe in dead water. Let this trench deepen gradually as the ground descends; so that at the intended foot of the pond it should sink nearly three yards, while the upper part thereof is kept shallow. Dig from either side of your trench, keeping its slope and level until within four fathoms of the intended margin of the fishpond. When this is done, turn your attention to what is called the dam-head, at the outlet or lowest part of the pond. From it continue your trench for a short distance in the form of a paved sluice. Build stones, grass-sods, and clay, along the bank on each side, if needful, and drive in a few piles to strengthen it. Then set a floodgate at the outlet, and another to serve as a check in case of accident, three yards further down, where your paved sluice terminates. A few cart-loads of coarse channel, not from the sea, ought to be emptied over the earthy parts of your pond, which otherwise are apt to get covered with weeds, or else to encourage eels, the marked enemies of trout in all stages. After this is done, let loose your stream, and form your preserve, introducing trout of about six inches in length, eight or ten to every acre. Raise also at the head a small nursery of minnows, connecting it by distinct sluices both with the pond and its feeder. These are favourite food of trout, and fatten them at a quick rate.'

We have read with great pleasure *The Practical Angler*, a little book full of really useful information, written by Mr Stewart, and published by A. and C. Black, Edinburgh. The book applies to *trout-fishing*, more particularly applied to clear waters; and the directions conveyed are plain, and to the point.



French Pisciculture.

FISHERIES.

WHETHER considered in reference to the natural history, the manual operations, or the economical advantages they involve, the marine fisheries of Britain form a subject of no inconsiderable interest. To the naturalist, the specific characters of the fish, their food, their migrations, and the seasons at which they become proper objects of capture, are points of attractive inquiry; while to the economist the various modes of capture and curing, the whole art, in fact, by which an unlimited natural production may be converted into a cheap and available source of human comfort, are matters of high importance. The present sheet is an attempt at a brief exposition of a branch of our commerce which is not yet well understood, either by the general public or the political economist. A complete view of the fishing interests of Great Britain naturally divides itself into two portions, the one comprising the *food*, and the other the *oil* fisheries. Deeming the food question to be of the greatest moment, we prefer devoting the greater part of our space to a review of this particular branch of our national industry—the whale and seal fisheries being of comparatively minor public interest.

I. THE FOOD-FISHERIES.

The river and sea fisheries of Great Britain are of the very greatest importance to the wellbeing of the people, whether we view them as a source from which may be drawn unlimited supplies of cheap and nutritious food, or as an outlet for the remunerative investment of a large amount of capital, and for the employment of a large body of the population. It must ever be a subject of regret to the economist that the proper development of this great source of national revenue has hitherto been much neglected. Even yet, after the lapse of centuries, we are apparently but beginning to appreciate the resources of the food-magazine which nature has placed at our command in the seas and rivers of this country. Although the development of our fisheries as a means of commerce is of comparatively modern origin, fish has been used as an article of food from the earliest ages. The rude means of capture at one time adopted, when the object was only to satisfy individual wants, have given way in the face of advancing civilisation to refined ingenuity; and the art of man has invented a machinery of nets and boats capable of capturing the finny tribe in quantities sufficiently numerous to supply in some degree the food-wants of our rapidly increasing population, and to make our fisheries no mean source of national commerce. Modern enterprise is also likely to greatly increase these supplies. Within a brief period, no less than three different companies have been started with the view of carrying on operations on a larger scale than has yet been attempted by private enterprise, and others, we hear, are projected; and for the purpose of bringing to their aid all the advantages of modern discovery, the steam-engine will be used, both as an assistant in the capture of the fish, and as a means of more speedily laying it before the public. That there will be an ample demand for the additional

fish-food that improved modes of capture may bring into the market, is quite certain. Fresh fish is rarely seen in many of our inland towns, and when a supply does make its appearance, it can be considered only as a luxury for the tables of the more opulent classes.

Some idea of the quantity of fresh fish consumed in the United Kingdom may be gathered from the following statement of what is sent to London alone. Our information is derived from an article entitled 'The London Commissariat,' which appeared in the *Quarterly Review*, No. CXC. It informs us that the railways are now, as may be expected, active agents in the conveyance of the metropolitan fish supply, and that, in addition to what arrives by means of the fishing-luggers and smacks, the Eastern Counties Railway forwards every night in the season 100 tons of herrings and other fish—or in all, 12,081 tons annually. 'The South-western Railway sends up annually, with the same speed, 4000 tons of mackerel and other fish, the gatherings of the south coast. The North-western collects overnight the "catch" from Ireland, Scotland, and the north-east coast of England, and adds to the Thames Street mart 3578 tons, principally of salmon; whilst the Great Northern delivers to the early morning-market, or sometimes later in the day, 3248 tons of like sea produce. The Great Western brings up the harvests of the Cornish and Devonshire coasts, chiefly mackerel and pilchards, to the amount of 1560 tons in the year; and the Brighton and South Coast conveys the incredible number of 15,000 bushels of oysters, besides 4000 tons of other fish.'

In Mr H. Mayhew's admirable work, *London Labour and the London Poor*, an estimate is attempted of the total quantity of fish sent to the London market, which we take the liberty of transcribing:

Description of Fish.	No. of Fish.	Weight of Fish.
Wet Fish.		lbs.
Salmon and Salmon Trout (29,000 boxes, 14 fish per box),	406,000	3,480,000
Live Cod (averaging 10 lbs. each),	400,000	4,000,000
Soles (averaging ¼ lb. each),	97,520,000	26,880,000
Whiting (averaging 6 oz. each),	17,920,000	6,720,000
Haddock (averaging 2 lbs. each),	2,470,000	5,040,000
Plaice (averaging 1 lb. each),	33,600,000	33,600,000
Mackerel (averaging 1 lb. each),	23,520,000	23,520,000
Fresh Herrings (250,000 barrels, 700 fish per barrel),	175,000,000	42,000,000
Ditto in bulk,	1,050,000,000	252,000,000
Sprats,		4,000,000
Eels from Holland (principally), England, and Ireland (6 fish per lb.),	9,797,760	1,505,280 127,680
Flounders (7200 quarterns, 36 fish per quartern),	259,200	43,200
Dabs (7500 qtns., 36 fish per qtn.),	270,000	48,750
Dry Fish.		
Barrelled Cod (15,000 barrels, 40 fish per barrel),	750,000	4,200,000
Dried Salt Cod (5 lbs. each),	1,600,000	8,000,000
Smoked Haddock (65,000 barrels, 300 fish per barrel),	19,500,000	10,920,000
Bloaters (265,000 baskets, 150 fish per basket),	147,000,000	10,600,000
Red Herrings (100,000 barrels, 500 fish per barrel),	50,000,000	14,000,000
Dried Sprats (9600 large bundles, 30 fish per bundle),	288,000	96,000
Shell Fish.		
Oysters,	495,896,000	
Lobsters (averaging 1 lb. each fish),	1,200,000	1,200,000
Crabs (averaging 1 lb. each fish),	600,000	600,000
Shrimps (324 to a pint),	498,428,648	
Whelks (227 to half-bushel),	4,943,200	
Muscles (1000 to half-bushel),	50,400,000	
Cockles (2000 to half-bushel),	67,392,000	
Periwinkles (4000 to half-bushel),	304,000,000	

Fish, as an article of diet, yields much nutriment, and is greatly esteemed by all classes; of all substances used as food by mankind, it is perhaps the most liable to get into a state of putrefaction, and should therefore be eaten when fresh. Those fish that are whitest and most flaky when boiled, as turbot, soles, cod, haddock, whiting, and flounders, are most easy of digestion; those which abound in oily matters, as salmon, herrings, and eels, are more nutritious, but not generally so digestible. As to the relative nutritive properties of fish and other animal food, Professor Brande states that 'when the muscular parts of animals are washed repeatedly in cold water, the fibrinous matter which remains consists chiefly of albumen; and is, in its chemical properties, analogous to the clot of blood.' Muscle yields also a portion of gelatine; and the flesh of beef and of some other animals affords a peculiar substance, of an aromatic flavour, called by Thenaud *osmazone*. Albumen and gelatine, then, constitute the leading nutritive ingredients in the different kinds of flesh used as food, and it is important to observe that their relative proportions are not very dissimilar in quadrupeds, birds, and fishes, as shewn in the following table. The water was determined by evaporation in a close-covered vessel, or at a temperature below 212°:

100 Parts of Muscle of	Water.	Albumen or Fibrin.	Gelatine.	Total of Nutritive Matter.
Mutton,	71	22	7	29
Chicken,	73	20	7	27
Beef,	74	20	6	26
Veal,	75	19	6	25
Pork,	76	19	5	24
Cod,	79	14	7	21
Sole,	79	15	6	21
Haddock,	82	13	5	18

According to Johnston, fish in general is less rich in fat than flesh meat.

Fish, when *out of season*, are unwholesome and not good: they are said to be sick; but, by a wise provision, the time varies with the different kinds of edible fish, so that some may be had good at all times throughout the year. The following table is applicable to the British markets, and enables us to see at a glance what fish are in season and what kind are out of season, during every month of the year; and also which kinds are in their best state for present use:

FISH TABLE.

S denotes that the Fish is in Season; F in Finest Season; and O out of Season.

* In the Firth of Forth, muscles are collected all the year round, but they invariably fall off in condition during the prevalence of easterly winds.

THE SALMON-FISHERIES.

Although not the representative of so large an amount of capital as some other fish, the salmon is of great value, and is considered one of the luxuries of the table. During late years, the decline in the British salmon-fisheries has become so notorious, as to be now attracting very great attention. At one time, this fish was exceedingly plentiful; so much was this the case, that in many of the towns of Ireland and Scotland, it was retailed at the cheap rate of 2d. per pound. Of course, it is many years since these prices were current; the opening up of the distant markets of London, and even those in the cities of the continent, consequent upon the introduction of steam-transport, soon placed salmon on a par, as to price, with venison and other game. The opening up of so many new markets has induced more active fishing; and no doubt this has been one of the causes of the declining supply of our rivers of late years. The rental of our best waters has fallen, in some instances, to one-third of what it was in former years, when this fish was captured in hundreds instead of in tens, as at present. As to over-fishing, the salmon proprietors are beginning to find out their error; at a meeting of the Tweed commissioners, held in October 1856, Lord Polwarth called to mind his having said, thirty years ago, that 'they were living upon principal and interest, a system which would ruin any property.'

The modes of taking salmon are various; differing according to the nature of the locality, be it sea-shore, tidal estuary, or running river. Along the shores of the open sea and estuaries, the salmon is continually traversing and retraversing during summer, and in such situations the stake-net is generally employed. This consists of a long wide-meshed net, supported on poles, which runs seaward in a straight line between high and low water-mark. From this main line various bending offsets are made, so as to form chambers or traps. As the fish push along shore, they are intercepted by the main line of net, and find their way into one or other of the traps, from which there is no retreat. Higher up the rivers, sweep-nets are used, one end being made fast to the shore, and the other run rapidly out by a boat, so as to enclose any fish that may be seen ascending. As soon as a salmon is observed by the outlook, a signal is made, the net run out as described, and then dragged on shore, encircling the object of capture. The central portions of wide rivers are usually worked by fishermen in boats called *cobles*, with long sweeping seine-like nets—a laborious, but not unsuccessful process. Still higher up, in certain rivers, weirs or dams are built, with enclosed places in the dam-wall called *cruives*. The fish as they push up the stream, enter these spaces, through which the water rushes, and are prevented by a grating of peculiar contrivance from getting out. In some places, stages are erected, from which fishers with bag-nets intercept the ascending salmon; and at linns or waterfalls, spearing is occasionally resorted to. By one or other of these methods immense numbers of salmon are annually taken.

The salmon is a victim to the depredations of pirates of all kinds, more than any other fish, and this is suggested as being another of the causes of its increasing scarcity. The spawn is exposed to the greatest injuries which the floods in the breeding-rivers can inflict; whole beds of it being carried away by the 'spates' of winter, long before the egg has time to be hatched. And if fortunate enough not to be swept away by the flood, the eggs or ova become the prey of trout, worms, the larvæ of insects, and water-fowl, or are parched by the sun, if the water which covers them should happen, as is often enough the case, to be dried up, or run into a new channel. Even when spared from all these perils, the instant it is hatched the fish is exposed to new dangers; and more especially in the state of the parr is it destroyed in thousands, becoming the easy prey of every juvenile angler in the neighbourhood of our salmon-rivers. Instances, indeed, are known where these valuable fry have been caught in incredible numbers, for the purpose of feeding the swine of the neighbouring cottagers.

There are also many other causes which may have influenced the declining supply; prominent among these we would rank the enormous destruction of grilses, and the annual massacre of the spawning fish. When we find, as is frequently the case, that the capture of grilse at some of the fishing-stations far outnumbers that of salmon, and when it is considered that not one of these fish has been allowed to deposit its spawn before being killed, it will be at once seen how much this will in time affect our supplies. Each of these grilses, which the greed of profit induces people to kill before they are allowed to breed, will average from four to five pounds' weight, and as the spawn is supposed to average 1000 eggs for each pound the salmon weighs, the number of future fish which are thus destroyed must be immense. For instance, during the last five years, the take of grilse on the Tweed has been, in round numbers, 140,000; in former years, it has averaged much higher than that; but if we assume the spawn in each of the female fish at 3000, and take two-thirds of the number as females, or take 100,000 as such, the quantity of eggs thus destroyed would be nearly 300,000,000. If we suppose even a hundredth part of this number of eggs allowed to grow up and reach the fishmonger's shop in the shape of full-grown salmon, we may see how completely the salmon-proprietors have been exemplifying the proverb, and killing the goose that laid the golden eggs. Another evil with which salmon have to contend, is the system of netting and leistering which prevails, and which is most resorted to in the breeding-time. The rivers are now so well watched as to have rendered the practice more infrequent than it was in the days of Sir Walter Scott and the Ettrick Shepherd, both of whom have described it with great power. Still, there must be a considerable loss from this source of illegal capture, as we have the means of knowing that salmon-poaching and the sale of foul fish are still carried on to a large extent. At the meeting already alluded to, the Duke of Buccleuch stated, that in the upper part of the Tweed—and we take it as an example—there was an enormous and wholesale destruction of fish. It was only by his own exertions and personal influence, he said, that immense destruction was prevented in the Ettrick and Yarrow, where the peasantry thought they had a 'right' to kill the fish when they could get them.

'The whole matter,' says a recent writer in the *Quarterly Review*, 'has been one of dispute for more than two centuries; but all are now agreed, that a timely cessation from wholesale slaughter is indispensable. The owner of fixed nets at the river's mouth keenly urges the propriety of allowing it to commence in the earliest part of the year, when salmon first approach the estuaries—are in the primest condition—and when, as they are scarce, the price in the market is high. As his "engines" have, owing to their position, the priority of capture, an early commencement would enable him to secure a large proportion of the best fish. On the other hand, the public fishermen of the tideway, the more inland landowners, the lessee of the solid weir, and those gleaners, the anglers, all oppose an early commencement, as depriving them of their chance for the bounty which nature directs towards them at a later period. They desire that the open season should not commence until the fish begin their ascent. But they often fall into the extreme of wishing to continue to fish too late: at that period when salmon is plentiful enough, but when its presence in the fresh water proves that it is hardly fit for food. Whatever may be the fence-months, the lower proprietor must enjoy the advantage of his position: but the law, as it stands at present, has given him a degree of monopoly,

in permitting his nets to commence operations at the earliest time at which salmon enter the rivers, and to continue as late as any higher up (except the anglers) may fish.'

Remedies are now anxiously sought for this state of things; and attempts are making to stock our rivers afresh by artificial means. Considerable results have already been achieved, by the experiments in 'pisciculture' (see ANGLING) at Stormontfield, on the river Tay, near Perth; and there can be no doubt that, if these be persevered in for a sufficient length of time, the supply of this fine fish will be sensibly increased; as the ova, when deposited in the usual way, are exposed to great danger, as we have already described; and every process which is calculated to shield either the eggs or the young fish from danger, must evidently be an aid in the multiplication of the species.

The greater part of the salmon taken in the rivers of Scotland and Ireland is at once despatched to London and the other large towns of the kingdom; part is also exported to the continental cities. It is usually kept fresh by being packed in ice; formerly, salmon was mostly disposed of 'cured,' and in its dried and pickled state a large trade was carried on with various Catholic countries, where it was much in demand during Lent. In Scotland, and also in England and Ireland, about the end of last century, this fish could be purchased in a wholesome condition at the low price of one penny and twopence per pound-weight. Then, in every farmhouse near the salmon-rivers, 'the venison of the waters' was a constant dish; and every peasant had his barrel of pickled, or his row of smoked salmon. Now, there is no such thing. No article of food is so rare; and a large fish is more valuable in London than a good fat sheep. In England, there are no fisheries for salmon that are worth naming. Most of the rivers have been long exhausted; and a Thames salmon, it is said, would be almost priceless. There are splendid salmon-rivers in Ireland, and some of the streams in that country still yield a very large supply of fish for the Liverpool and London markets, as well as for home consumption. It is difficult to ascertain accurately the produce of the Irish salmon-rivers in recent years, but that previous to 1842 the 'take' of fish was considerable. A writer on the subject says the average annual take of salmon at that period may be reckoned at 200 tons for each of the chief fisheries. 'The Foyle fishery in 1842 produced nearly 300 tons; and it is a remarkable fact that, in the reign of Charles I., the produce of the Foyle is stated at 240 tons for the year 1638; the Bann at Coleraine previously, also, had been equally fruitful; and the Shannon superior to all. Shortly anterior to 1842, in one town on the Shannon—the town of Glin—£8000 worth of salmon was sold in one season. The great fishery of the Moy, at Ballina; the Blackwater, at Lismore; and last, though not least, the Erne, at Ballyshannon, produced also their hundreds of tons.' The writer to whom we are indebted for these statistics —Mr Worthington—tells us in a part of his volume that these fisheries are now in a state of comparative decay, doubtless from the same cause which has affected our Scottish rivers — injudicious and over fishing, poaching, &c.

Very large rentals were at one time derived from the Scottish salmon-fisheries; in fact, the rent of some fishing-stations, and these perhaps small in extent, greatly exceeded that of a farm of hundreds of acres. And be it recollected this valuable property cost the landlord very little expenditure in return; there was no expense incurred for farm-buildings, for draining, for fences, and other sources of outlay incurred by land. The value of those fisheries has greatly declined of late years; if we take the Tweed as an index to other rivers, we find that its fishings, which were rented in 1814 for £20,000, now produce only a fourth part of that sum; and the number of boxes of salmon at present despatched from Berwick-on-Tweed is only 3000, whereas five times that quantity has been known to be sent. But, notwithstanding all this falling off, the supply of salmon sent to London alone is still very considerable. Mr Saunders, a practical authority on such subjects, estimates it at above £100,000 per season for fresh fish only.

If we except the far-famed Lochleven trout, there is not in Great Britain any commerce worth mentioning in fresh-water fish, besides the salmon and the salmon-trout.

Artificial Fish-breeding.

Were the French system of repeopling the waters by means of pisciculture, adopted in our numerous lochs and streams, a very large extension of the fish-trade might be looked for, and a considerable addition made to the existing varieties in the fish-market. The frontispiece gives a view of the fish-hatching apparatus exhibited at the Paris Agricultural Show, which represented the experiments carried out by the French government for restocking their principal rivers and lakes. Many of the rivers of France and Germany have been rendered valuable by means of this system of artificial hatching and nursing, introduced by Gehin and Remy, and there are no obstacles to a similar development of the river-fisheries in Great Britain. By this means, in addition to multiplying our present stock of fishes, new species might be introduced—as the ova can be packed and sent to any distance with great facility.

We are glad to observe that arrangements are in progress in various parts of Great Britain, for the further development of our fresh-water fisheries. A Salmon Fishing Company, on the limited liability principle, has commenced operations on the beautiful river Dart, in Devonshire. It has been planned, we understand, by Mr Gottlieb Boccius, and the system of artificial rearing will be here carried on to a large extent. If successful, we have no doubt of its giving rise to numerous other enterprises of a similar kind. The rivers, canals, and lochs of Scotland are particularly favourable to an extensive cultivation of fresh-water fishes. A writer on 'Salmon' in the *Agricultural Journal* for March 1857, throws out the following suggestions on this part of the fishery question: 'In Scotland, we have about 180 miles of canals. Why are they fishless, when they might be easily stocked with many valuable species of fish? Why do the Water Company (of Edinburgh), owners of the Compensation Pond among the Pentland Hills, not encourage the breed of so valuable a fish as the sea-trout? Why not try to swell their annual dividend by the introduction into their capacious reservoirs of the species of salmon so abundant in Lake Wenern!' The writer also suggests the Loch of Lindores, 'within half an hour's journey from the populous towns of Perth and Dundee, and distant from Edinburgh and Glasgow not more than two and four hours respectively,' as a fitting locality for experiments in pisciculture; and he further recommends the introduction into Britain of the delicious Canadian fish called the black bass. 'This is one of the finest of the American fresh-water fishes. It is surpassed by none in boldness of biting, in firm and violent resistance when hooked, and by a very few only in excellence upon the board. It bites ravenously at a small fish or minnow tackle, and also affords excellent sport with an artificial fly. It attains the weight of six or eight pounds.' The success of the experiments performed at Stormontfield, in a commercial view, are quite conclusive, as the following memoranda, gathered from the books of the superintendent, will at once demonstrate:

1. Of the marked fish which were liberated from the pond at Stormontfield, four out of every hundred were recaptured, either as grilse or salmon.

2. We find that more than 300,000 fish were reared

in the pond, and allowed to go into the Tay. Thus, 40 fish out of every 1000 were recaptured; and as 300,000 were in all liberated, it follows that 12,000 of the salmon taken in the Tay were pond-bred fish. But, as the fish did not all go away in one year, this 12,000 must be distributed over two years.

3. We find the average number of salmon and grilse taken in each year is 70,000. It follows, then, if there be any truth in figures, that nearly one-tenth of the fish taken in the Tay for the last two years were artificially bred. This is equivalent to a rise of 10 per cent. in the rental of the fishings; and such, we find, is the result.

THE HERRING-FISHERY.

There is perhaps as much mystery attending the natural history and habits of the herring at the present time, as there was about those of the salmon forty years ago. It is ranked by naturalists in the same family with the pilchard, sprat, shad, anchovy, and white-bait. The body, which is about ten or twelve inches in length, and of a handsome, regular shape, is covered with thin roundish scales; the upper part is blue or green, according to the light, and the lower of a silvery white. The belly is carinated, but not serrated, as in the sprat—a distinction which is obvious and permanent. Owing to the gill-covers being very loose, and opening wide, the animal dies almost the instant it is taken out of the water. Even in the nineteenth century, we have not entirely got over the ancient and once popular myth of this fish being a native of the great arctic seas, and instinctively rushing, at the proper season, in vast shoals to these islands, in order to be captured and become the food of man. Naturalists, however, now know as much of the habits of this fish as to be able to refute the old theory, and to state with certainty that it spawns upon our own coasts; but where it proceeds to after accomplishing this process, is somewhat doubtful. Some naturalists aver that the herring never leaves our own seas, but that, after the season of spawning is over, it merely retires from the shores into deep water. This again is denied, as, were it really the case, the cod and ling found in the deep sea would certainly prey upon it; but this, it is ascertained, is so rarely the case, as to lead to the conclusion that the herring do not rendezvous even in the deeper parts of our own seas. A writer on this subject says: 'The larger herrings, of which the great western shoal is composed, seemed to wander, while in the state of fry, to the Northern Ocean, whence they return periodically, on coming to maturity. This is inferred, because it is certain the further north, the earlier this fishing commences; and because the shoal, when it first comes, is always attended by arctic gulls, whose plumage differs from that of the common herring-gull on the coast of Scotland.'

The herring-fishery, when pursued on a large scale, is carried on by means of what are called *drift-nets*, the meshes of which are regulated to an inch in size by act of parliament. A single net is generally about fifty feet long, and from thirty to thirty-five feet in depth, and the cost of it is from £4 to £5. For the purpose of capturing the fish, the various nets are joined together into what is termed a *train*, which may run to any length, but is generally from 500 to 2000 yards—long trains being preferred to short ones. The whole is held in position by the *back-rope*, a strong cord running along the back of the train, and which has fixed to it the buoys, which keep the netting afloat. The train is held down in the water by means of weights. The boats necessary for carrying such a load of netting, it is obvious, must be of considerable value; the best class of them costing upwards of £100.

The boats arrive at the proposed fishing-place in the evening; the nets are shot after sunset, as the fish always strike best in the dark; and the catch takes place throughout the night. The process of throwing a train of nets into the sea is quite simple: it is *paid* over the stern of the boat, which is slowly rowed over the part of the sea selected as being most likely to be in close proximity to the shoal. When all the nets forming a train have been shot, a rope about twenty fathoms long, which is technically called the *swing-rope*, keeps the last one attached to the boat. Sometimes the other end of the train of nets is fastened to an anchor, or it may be to the shore, when that plan is convenient; but more generally the whole length is only fastened by the swing-rope to the boat, and is allowed to float slowly along, carried away by the tide or current—a great perforated wall, 2000 feet long, and 24 feet deep, standing upright in the water. When the shoal, in its progress, comes against this barrier, the fish are caught by what is called *meshing*—that is, by thrusting their heads through the interstices of the net, and being entangled by their gills. Sometimes the fish have to be waited for long, and perhaps, after all, none may be got that night; while at other times a heavy take may occur in less than an hour. To ascertain whether or not the fish may have struck the net, a custom exists of *preeing* the nets—that is, lifting out a portion of a train and examining it. If there be no appearance of fish, the labour of hauling in the nets, removing to a new spot, and again shooting, has to be undergone, in the hope of being at last lucky enough to hit upon a better spot. Supposing the fish to have come upon the train of nets, the process of hauling into the boats and taking the herring out of the meshes, is commenced. Formerly, it used to be the practice just to haul in the net, and leave the fish sticking in it by the gills till the boat landed; now, as the nets are hauled on board, the herrings are carefully shaken out, a decided improvement on the old plan, which frequently mutilated the fish to a very serious extent.

The town of Wick in Scotland, may be said to owe its existence to the herring-fishery; in fact, the popular saying of being founded on herring-bones is as applicable to the thriving town of Wick, as Amsterdam. It possesses a large population, all engaged more or less in the fisheries; and the capital represented by boats, nets, &c., amounts to nearly £60,000. The greater part of the fish taken at Wick are cured for exportation—a trade requiring a large amount of tonnage, and upwards of 1000 men to carry it on. The gutting and packing also, give employment to a great variety of persons, chiefly women, as well as to a number of boats which convey salt from Liverpool, as well as from foreign ports. The whole process of curing may be seen in Wick to the greatest advantage; and it has been thus described:

'When the herrings are captured, and the boats reach the harbour, the process of curing them begins. Immediately on their arrival, the fish are carried to huge but shallow gutting-tubs prepared for their reception. Once there, they are operated upon by a band of females, who gut them with a rapidity which is quite extraordinary. One thousand fish in an hour being the common work, it may be readily conceived that, when a large number of hands are employed, an immense shoal can be disposed of in a few hours. The women employed, usually work together in a little band of four or five, each performing a part of the labour which is necessary, some carrying, some salting. After the fish are eviscerated, which is rapidly performed by two simple movements with a knife, they are transferred to another vat or trough, where they are laid down in layers of alternate salt and fish. The sooner the herrings are sprinkled with salt, the better for the *cure*. Then they are *roused*, as it is called—that is, a stick or a brawny arm mixes them well together—a process repeated at intervals till the trough is filled. After a brief rest, depending much on circumstances as to its length, the herrings are carefully resalted, and then packed into barrels, either flat on their sides—to suit the Irish market—or backs

downward, to please the foreigners. Every row, as it is put in, is well sprinkled with salt. A week's rest is allowed before the barrels are finally headed up, as the fish settle down so much as to admit of an additional quantity being put in. When intended to receive the brand of the Fishery Board, the barrel must remain open for ten days.'

The annual reports of the Commissioners of British Fisheries give ample statistics of the herring-fishery. From the tables compiled in these documents, we perceive that, amid considerable fluctuations, there has been a gradual increase for the last fifty years in the quantity of fish cured, and the quantity exported. Of course, there is no account of what has been consumed in a fresh state, as that has not been taken cognizance of by the officers of the Fishery Board. The year in which the reports commence is 1809, when the total quantity cured was little more than 90,000 barrels; in 1810, the amount is nearly the same; but after that period it rapidly increases, till the quantity is measured by hundreds of thousands of barrels. The three highest years are as follows: 1850, 770,698 barrels; 1853, 778,089 barrels; 1855, 766,988 barrels. The total quantity of herrings cured during 1856 was 609,988½ barrels; the total quantity branded, 223,281; and the total quantity exported, 347,611¼—being a decrease upon the preceding year of 156,715 barrels in the quantity cured, of 57,300¼ in the quantity branded, and of 94,652¾ in the quantity exported. From the account of the herrings caught, but not cured, it appears that the quantity in 1856 amounted to 107,685 barrels or crans—being a decrease upon the preceding year of 23,074 barrels or crans; and when this account is added to the amount of herrings cured, the total produce of the herring-fisheries for 1856 amounts to 717,673½ barrels—being a decrease upon the preceding year of 179,789 barrels or crans.

The herring-fishery has, from a very early period, been a source of wealth to this country, particularly to Scotland. Evidence of the fact is to be found in the ancient acts of parliament, and in various other historical documents. 'It appears from a manuscript of Sir Robert Sibbald, that, before the Union, 600 boats, with above 4000 men, have been seen at once employed in the herring-fishery in the Firth of Clyde alone, which afforded in a year 3750 tons of herrings for exportation; that a small tract upon the coast of Fife, not above twelve miles in length, fitted out 168 boats, manned with 1120 fishers, and usually exported about 12,000 barrels of herrings; and that in the year 1695, the small town of Crail in Fife, exported above 2400 barrels. What quantity was exported from the whole of the Forth, from the Murray Firth, where the fishery was still more considerable, and from other parts of the kingdom, does not precisely appear; but from general report, it seems to have been great, compared to what it has been ever since. . . . After the Union, the enactment of the salt-duties, and the complicated regulations established for their management; the difficulties in obtaining salt, and the great risk incurred by traders entering into salt bonds, at once depressed the fisheries of Scotland, which for some time had worn the most promising appearance.'

The amount of capital at present invested, and the number of people employed in the Scottish herring-fishery, are very considerable. The boats, netting-lines, and other equipments—are valued (1854) at upwards of half a million sterling. The amount is thus divided: boats, £225,830; nets, £303,666; lines, £57,924. The boats engaged in the Scotch fisheries, including a few hundreds from the Isle of Man, make a fleet of 11,000; and the number of persons engaged in the trade cannot be less than 70,000. The number of fishing-luggers belonging to Great Yarmouth is said to be about 300, carrying ten men each. These vessels are chiefly employed in the mackerel and herring fisheries during their seasons. There are also a number of trawl-fishing smacks belonging to the port, and upwards of fifty boats employed in the shrimp-trade. M'Culloch estimates the capital invested at Yarmouth and Lowestoft at a quarter of a million sterling. This latter place employs about seventy boats, of forty tons each. The greater number of the herrings taken at Yarmouth and other places are cured in Manchester, and known in London and throughout England by the name of Yarmouth bloaters. It may likewise be mentioned that Hastings and Folkestone on the English coast have capital herring-fisheries, and that a large portion of the fresh fish which reaches the metropolis is sent from these towns; they are also caught in Cardigan and Swansea Bays. The Irish herring-fisheries are not worked as they ought to be; hence Ireland, although its coasts abound with fine fish, derives the chief portion of its herring supply from the north of Scotland.

THE PILCHARD-FISHERY.

The pilchard is not unlike the herring, and was at one time caught in the principal Scottish estuaries. Up to the year 1816, it used to be taken in great quantities in the Firth of Forth. At the present time, the principal resort of this fish is the coast of Cornwall, where its capture gives employment to a large number of people, and a considerable amount of capital is required to carry it on. The following account of this fishery is abridged from a graphic letter which appeared in the columns of a provincial newspaper:

'This fish is nowhere seen but on the coast of Cornwall, and is only to be found for a brief period of two or three months. They arrive to the eastward of the Land's End about the end of July, and they continue to the beginning of October. They are afterwards seen on the north coast of the county, where the fishing is carried on for a few weeks later. They then disappear, and whither they go is as yet unknown to naturalists, but they are supposed to come from the Atlantic. The size of the shoals and the closeness to which they approach the shore vary much in different years, making the fishery rather a speculative undertaking. Notwithstanding a comparatively good year now and then, this branch of our fisheries is not so important a source of wealth to Cornwall as it was forty or fifty years ago.

'An account of the manner in which the fish are caught and cured may be interesting to those who do not already know it. They are fished for in two ways: by *seines*, in which far the greater number are taken; and by *driving*. The latter is similar to the mode followed for the capture of herrings. The pilchard *driver*, or boat, is deep, square-sterned, and generally yawl-rigged. Like the herring-boats, they can stand heavy weather, and sail remarkably fast. But the seine-fishing is something novel; and the fish taken in this manner bring the highest price in the foreign markets. A seine, with the necessary boats, grapnels, and gear, costs about £1500. From the amount of outlay which is required, they are generally the property of capitalists, but are sometimes held by a company, and divided into small shares. Twenty men are employed on each seine, who are paid by small wages—generally eight shillings a week—and a share in the profits. The seine measures in length 220, and in depth from 16 to 18 fathoms. On one edge are placed corks, and at the other leaden weights; and this enormous net is carried in a large boat or lighter, and thrown overboard so as to encircle a shoal of fish when they can be found in water not deeper than the seine. As soon as the fish are surrounded by this hempen wall, anchors are carried away from different parts of the seine, and it is safely moored; and unless stormy weather comes on, the fish may be kept there, and taken out at leisure. At Mevagissey, on one occasion, when salt became scarce, the seines were left in the water, and the fish kept alive till a vessel went to Normandy and brought back a cargo of salt. The fish are lifted out of the enclosed space with a smaller net called the *tuck-seine*.

This is done at low-water and at night, as the fish during the day remain near the bottom, and any attempt at raising them would result in the tearing of the net. *Tucking*, or lifting out the fish, is thus accomplished: The boats in which the fish are to be carried are brought close to the seine, and the small net is drawn tight; two men sit on the gunwale, and with a two-handled basket lift the fish and pour them into the boat. The strange silvery light caused by the living mass of fish, the joy of the fishermen, which breaks out every now and then into songs and shouts, which are echoed from the bold cliffs in the vicinity, make this part of the operation beautiful and interesting. A shoal of fish changes the colour of the water; and this is observed most easily an hour before sunset, at which time the seiners are all silent, and intently watching the water. Much depends upon the eye and judgment of the master-seiner, who accompanies the larger boats in a small boat called the *lurcher*. If the seine should enclose 200 hogsheads, it is considered a successful shot; but as many as 1500 hogsheads have been surrounded by a seine at one time. It, however, often happens that the fish are travelling so rapidly through the water, that they escape whilst the men are casting the seine overboard.'

The average number of hogsheads exported is about 25,000 per annum; and the wholesale price may be stated at £2, 10s. per hogshead. Each hogshead contains about 3000 fish. The fishery varies very greatly. Instances have been known of quantities sufficient to fill 10,000 hogsheads being taken ashore in one day.

The following is the mode of dealing with the fish after they are captured. When they are intended for exportation, they are carried into cellars and *bulked*—that is, laid in rows in a heap, with a layer of salt between each layer of fish. After lying in the salt for a month, they are washed and packed into casks; but before the casks are *headed*, the fish are pressed down; the casks are then filled up, and again pressed; and after being a third time submitted to pressure, the casks are closed up, and considered ready for shipment. The fish being so pressed, keep much better in the warm climate to which they are sent, and a large quantity of valuable oil is produced. It is calculated that fifteen hogsheads of pilchards produce a hogshead of oil; so that the produce of this oil adds considerably to the value of the pilchard-fishery, as it sells for £42 per ton; and the scum, or garbage, as it is called, which rises to the surface in the washing-troughs, is purchased by the soap-manufacturers at about £10 a ton. The quantity of salt required is very considerable—eight bushels to every hogshead of fish—but the undissolved salt, which is more than half the quantity used, is sold readily for manure at 20s. a ton. A good year's fishing returns large profit to the curers, and supplies cheap food and remunerative employment to those engaged in its capture.

THE SPRAT-HARVEST.

The sprat, or, as it is called in Scotland, the garvie, is an important member of the *clupeidæ*, and is by some authorities described as the young of the herring—an opinion which is, however, scouted by others. After the errors which prevailed so long concerning the natural history of the salmon, we ought to be careful how we pronounce judgment on this subject; and as there is so much ignorance as to the herring itself, it is just possible that the sprat may be a young herring. The writer in the *Quarterly Review*, No. CXC., says, in speaking of this fish: 'Next to the herring-fishery, the sea-harvest of most importance to the poor of London is that of sprats, which come in about Lord Mayor's day; and it is a popular belief that the first dish is always sent to the chief-magistrate of the city. If a telegraph were to be laid down to all the alleys and courts, the fact of a large arrival of these little creatures at Billingsgate would not be sooner made known to the lower orders than by some mysterious process it is at present.'

As will be seen from our table, the sprat is in season for about three months—the fishing commencing in November; the greatest quantities are caught on very dark or foggy nights. Many thousand tons are sometimes taken; and, in lack of a better market, have to be sold at a few pence, to the farmers, as manure.

The far-famed white-bait is also a member of the herring family. It is a very small fish, of silvery lustre, and is found in the brackish waters of the Thames during the months of summer. It is also found in the river Hamble, which flows into Southampton Water, and, according to Parnell, it can be taken between Queensferry and Kincardine on the Firth of Forth in great quantities. White-bait dinners are in great repute amongst the aristocracy of London, who resort to Greenwich or Blackwall, to enjoy the fish in its finest condition. Pennant says of this fish: 'They are esteemed very delicious when fried with fine flour. They come into season about March or April.'

THE WHITE-FISHERY.

Under this term is included not only the fishery of the common cod, but that of the haddock, whiting, ling, hake, torsk, and others—all remarkable for the excellence of their flesh, which is white, firm, separates readily into flakes, is agreeable to the taste, and wholesome. They belong to the soft-finned fishes, and constitute a family of great extent and usefulness, known by the name of *Gadidæ*, and found in every sea but the Mediterranean. They live for the most part in the seas of cold or temperate climates; and from their size, and their tendency to congregate in particular localities, as well as from the value of their flesh, they are of great importance to man. As our space will not permit us to notice individually the members of this extensive family, we shall direct attention chiefly to the cod, as the head and representative—premising that the natural habits, modes of capture, curing, and preparation, are much the same in all.

The great seat of the cod-fishery is at Newfoundland and other places on the coasts of North America, and the trade there is mostly in the hands of the French and Americans. Vast quantities of this particular fish are caught, and are constantly imported into this country in a dried or cured state, constituting a well-known article of commerce. In Great Britain, the chief seat of the cod and ling fishery is in the north of Scotland, although great supplies are also found on the coast of Ireland, and on some parts of the English coast. The cod-fish is very voracious; a favourable circumstance for the fishermen, who experience little difficulty in taking them with almost any bait, whenever a favourable locality is ascertained. As these fish generally inhabit deep water—from twenty-five to forty, and even fifty fathoms—and feed near the ground, on various small fish, worms, crustacea, and testacea, their capture is only attempted with lines and hooks. The most common mode is by deep-sea lines, called *bulters*, on the Cornish coast: these are long lines, with hooks fastened at regular distances along their whole length, by shorter and smaller cords called *snoods*. The snoods are six feet long each, and placed on the long line twelve feet from each other, to prevent the hooks from becoming entangled. The line has an anchor or grapple and a buoy at each end, and is laid, or *shot*, across the direction of the tide; after being left for about six hours, it is hauled up for examination.

The fishermen, when not engaged in shooting, hauling, or rebaiting the lines, fish with hand-lines, armed with two hooks kept apart by a strong piece of wire. Each fisherman manages two lines, holding one line in each hand; a heavy weight is attached to the lower end of the line not far from the hooks, to keep the bait down near the ground, where the fish principally feed.

Vessels now sail as far as Davis' Strait and to the Faröe Islands for fresh cod, and quantities are carried alive in welled smacks all the way to London. Boats of this kind, for preserving alive the fish taken at sea, came into use in this country early in the last century. They are said to have been first built at Harwich, in 1712, by an ancestor of Mr Saunders, the fish-factor of Billingsgate; and it is remarkable that some of them were engaged in conveying troops at the time of the rebellion of 1715. The store-boats remain as far down the Thames as Gravesend, because the water there is sufficiently mixed to keep the fish alive. If they were to come higher up, the fresh water would kill them.

The greater part of the cod which are caught on our shores are brought to market as cured fish, and the process of curing is as follows: The fish are usually killed and cleaned as soon as taken. When brought on shore, they are opened up from head to tail, and a portion of the backbone is cut out. They are then carefully washed and purified from blood by copious libations of clean salt-water. After being drained, which is the next process, they are laid down in a long vat, in alternate rows of fish and salt, heavy weights being placed upon the layers, to keep them under the action of the pickle. After a time, they are taken out of the vat, again washed and brushed, and gathered into little heaps to drain. This being effected, they are spread out individually to *pine* by exposure to the sun and air. Next, they are built into heaps called *steeples*, to await the appearance of what is technically called the *bloom*, a whitish substance which comes out on the fish. This completes the business. In Yorkshire, the curers improve on this plan, by placing the fish on wooden erections made of cross-bars, which admits of their drying much sooner, keeps them cleaner, and obviates numerous accidents which occur to those dried on the ground.

Upon the cod and ling fisheries of Scotland, the commissioners, in their report for fishing (1855), say: 'The Board have to report that they shew an increase of nearly 10,000 hundredweights upon those of 1854, which, again, were an increase upon the preceding year. The exportation to Spain, in 1854, was 5630 hundredweights; in 1855, it was 14,520 hundredweights. Although the cod-fisheries can never be expected to be so productive, or to give employment to so many hands, as the herring-fisheries, they are valuable, and capable of considerable extension, especially if the import-duties in several of the fish-consuming countries of Europe were not so high as almost to debar the importation of British cured fish. The evils of a moist climate, which is most unfavourable to the cure of cod and ling, will always have to be contended against in this country; but a great deal more fish of a high character could be prepared if there were markets for them. Voyages to a considerable distance would be undertaken; and as a large fleet of French vessels proceeds to Iceland and the Faröe Isles, stimulated by the gain made in this fishing, from exclusive command of the French market, so, under more liberal commercial arrangements, the fishing crews of British boats might be encouraged to the like enterprise, and become, as the French do, skilful navigators from such long sea-voyages.'

The following statistics for the Scottish cod and ling fisheries of 1856, are from an official source: The returns shew that 110,504¾ hundredweights were cured dried, and 6642 barrels cured in pickle, and that the total quantity exported was 29,629¾ hundredweights—being a decrease in 1856, as compared with 1855, of 3056¼ hundredweights in the quantity cured dried, but an increase of 325½ barrels in the quantity cured in pickle, and also an increase of 475¼ hundredweights in the total quantity exported. The quantity of cod and ling caught, but not cured, amounts to 59,987 hundredweights, being a decrease upon the preceding year of 3552 hundredweights; and when added to the quantity cured, makes the produce of the cod and ling fisheries for 1856 to be 170,491¾ hundredweights, and 6642 barrels—being a decrease upon the preceding year of 6608¼ hundredweights, but an increase of 325½ barrels. Of course, in addition to all this, there must be taken into consideration the very large quantity caught of which no account is taken; and the total supply may be estimated from the fact, that from our home sea-fisheries alone, we get four millions of these fish! Cod is also to be had in very large quantities in the much-neglected Irish bays; and the coasts of Norway, we are told, absolutely swarm with the members of the cod family, and profitable fisheries are carried on there in the various fiords. This fish is usually referred to as one of the most remarkable instances of animal fertility—the eggs in one female sometimes amounting to the incredible number of 9,384,000. Cuvier says that 'the flesh of these fishes, which is white, firm, and of most excellent flavour, renders them exceedingly valuable to us. It is capable of being preserved in a state fit for eating much longer than that of other species of this class. Its consumption is consequently extended through the four quarters of the globe.'

There is a large commerce carried on in other members of the cod family, chiefly, however, in haddocks and whitings, which are much esteemed in a fresh state, as also when dried and brought to market, as the well-known Finnans. The haddock is found in large numbers in all the British seas, and is taken, like the cod, chiefly by baited lines; considerable quantities are also got by the use of trawl-nets in the deep-sea fisheries. It is supposed that the very finest are to be found in the inlets and bays of the sister-island. The smoked or cured fish are prepared in a very simple way, by most of the inhabitants of our fishing-villages. They are merely split up, the intestines are taken out, and they are then hung up in the chimney-corner, to be smoked generally by means of a peat-fire; as many as from 200 to 400 can be made ready in a batch at a fire-side of ordinary size. 'The commerce in this description of fish has greatly increased in Scotland,' says Mr James Wilson, 'many having embarked in it on a large scale, by erecting extensive curing-houses, and purchasing haddocks from numerous captors, who confine themselves almost solely to this department of fishing. The whole process, when performed upon the smaller scale, and by the country-people, takes only a few hours; so that fish caught in the evening may be in a market many miles distant on the morning of the following day. The real Finnans are generally small, and of a pleasant pale-yellow colour; but larger fish are cured at the great commercial stations, and in a way intended to admit of their being sent to a longer distance, and keeping for a longer time.' The Scottish markets used to have large supplies of the haddock; the quantity taken was sometimes immense; and hundreds of people found a livelihood in hawking it about the streets, where at one time it could be purchased for a mere trifle. Even yet, it is comparatively cheap in such towns as Edinburgh. In the *Gadidæ*—the family of the cod-fish—are included the common cod, the dorse or variable cod, the haddock, the bib, the poor or power cod, the speckled cod, the whiting, the coal-fish, the pollack, the green cod, the hake, the ling, the burbot, the three-bearded rochling, and the torsk or tusk, all of them good for food.

THE FLAT-FISH OR TRAWL FISHERY.

Pleuronectidæ, the family of the flounders, or flat-fish, includes many of our most esteemed table delicacies, embracing the aldermanic turbot, the delightful sole, the halibut, as well as brill, dabs, plaice, &c. This kind of fish is captured chiefly on the English coasts, the instrument employed being the trawl-net. Trawling is a very simple way of fishing, and well adapted for the taking of flat-fish, which are mostly denizens of the deeper parts

of our coast. The net employed in this method of fishing is in the form of a large bag open at one end. It is suspended from the stern of the fishing-lugger, which drags it at a slow pace over the fishing banks.

We have not space to give a separate account of each member of the flat-fish family, but we must notice one or two of the principal varieties, giving precedence to the turbot, which is in great request, in consequence of the exquisite flavour of its flesh, and which 'has exercised the skill and ingenuity of the great professors of gastronomy, in a variety of culinary preparations, from the time of Apicius down to that of Ude and Kitchener.'

Hamilton, in his work on British fishes (1843), says: 'The ordinary length of the turbot is from eighteen inches to two feet, and the weight from four to ten pounds. Individuals of 20, 30, 70, and even 190 pounds' weight have been met with. The extent of the demand for this fish in the London market appears from the fact, that the annual supply at Billingsgate has been 87,958. A preference is given to those brought by the Dutch, who are supposed to have drawn for many years back not less than £80,000 a year for the supply of this market alone. Up to the present year (1843), a duty of £6 was paid for each boat-load, which might consist of from 100 to 150. By the recent modification of the tariff, the duty has been reduced.' The turbot is scarce in the northern waters, rare at the Orkneys, and seldom seen among the Shetland Islands. We find them, however, at the mouth of the Forth; and on the coasts of Berwick, Northumberland, Durham, and York they have been plentifully taken. When trawling is unsuccessful, the line is resorted to; and 'vast stores of turbot are found in the Silver Pits between the Dogger and Well Banks, where hundreds of vessels may be found profitably engaged in its capture.'

As we have indicated, 'our London and home markets are largely supplied by the Dutch fisheries, which commence early in the spring-season; and neither the Scotch nor English pursue the fishery with the same success as our enterprising neighbours from Holland. As the year advances, the fish migrate to where deeper water is obtained, and where the line must be resorted to. The fishery terminates about the beginning of autumn. The coasts of Devonshire, and off Dover towards the French side, are all productive places for the taking of these kinds of fish. Soles have been caught of the great weight of nine pounds, and very frequently of five pounds' weight. Skate-fishing, which is much followed in the north, is similar to the other kinds of trawl-fishing.' The skate, however, belongs to a distinct family—the rays. 'In the Firth of Forth,' according to Dr Parnell, 'these fishes are met with in great numbers, particularly in the neighbourhood of the Bass and May, where they are taken in nets, and are often found on lines set in deep water for cod. In the spring months, the Edinburgh market has a daily supply, and so great is the demand, that no less than a dozen cart-loads are sold during the week.'

The commerce in all kinds of flat fish is very considerable, as may be inferred from the fact, that 97,520,000 soles passed through the great market of Billingsgate in the year 1850; and plentiful supplies reach London without being enumerated. The turbot supply of the same year was 2500 tons. Of dabs and flounders, 91,950 pounds' weight are recorded as used in the great metropolis alone. We may judge from these figures of the quantities likely to be consumed by the busy populations of those other large towns which are fortunate enough to procure the luxury of fresh fish.

THE MACKEREL-FISHERY.

The principal seat of this fishery is Great Yarmouth, on the coast of Norfolk, already alluded to in our account of the herring-fishery. A great part of the prosperity of this town has arisen from its fisheries. In 1853, about 90 boats were engaged at this fishery, and the produce of their two months' labour realised about £30,000. When the fishing-luggers come ashore with their cargo, it is at once disposed of by auction, and despatched in all haste to London, where, of course, there is a ready market at all times for any quantity of fish. The mackerel is a voracious feeder, and its growth rapid; but it is not the largest fish that are accounted best for the table. Those taken in May or June are considered superior in flavour to such as are caught either in early spring or in autumn. The mackerel spawns in June; and 540,000 ova are said to have been counted in one female. For the mackerel while roaming at large through the waters of the ocean, no successful mode of capture could be adopted; but at its periodical return to the coasts, millions are taken by the net, seine, or line, and yet the number caught is but a mere fraction of the countless shoals that escape.

The modes of taking this fish are, in general, the same as those employed in the herring-fishery, varied by the two other methods which are thus described by Mr Couch: 'The one by means of a long deep net, with small meshes, by which the fish are surrounded, and then either taken from the water by *flaskets*, or hauled direct to the land, in the manner of a ground-net; the other by means of a hook and line, called *trailing*. The latter forms a first-rate marine sport, and is thus performed—"The mackerel will bite at any bait that is used to take the smaller kinds of fish; but preference is given to what resembles a living and active prey, which is imitated by what is termed a *lask*—a long slice cut from the side of one of its own kind, near the tail. It is found also that a slip of red leather or piece of scarlet cloth will commonly succeed; and a scarlet coat has therefore been called a mackerel bait for a lady. The boat is placed under sail, and a smart breeze is considered favourable; hence termed a 'mackerel breeze.' The line is short, but weighed down with a heavy plummet; and in this manner, when these fish abound, two men will take from 500 to 1000 in a day. It is singular that the greatest number of mackerel are caught when the boat moves most rapidly, and that even then the hook is commonly swallowed. It seems that the mackerel takes its food by striking across the course of what it supposes to be its flying prey. A gloomy atmosphere greatly aids this kind of fishing."'

SHELL-FISHERIES.

There is an immense demand by all classes for shell-fish. Lobsters, crabs, crayfish, oysters, muscles, cockles, periwinkles (whelks), prawns, and other varieties, are constantly in requisition. Most of the lobsters brought to the English market are disposed of through the agency of Mr Saunders of Thames Street, who has great quantities of this crustacean delicacy consigned to him every morning from the fishermen of Norway, France, and the Channel Islands. This gentleman, it is said, deals in shell-fish to the extent of £40,000 per annum; nearly half of that sum being due to the Norwegian branch of the trade. The following is a description of the kind of vessel used for carrying shell-fish: 'The hold is divided into compartments, and in one division may be seen hundreds of lobsters; another compartment contains sea-crayfish, and next door to them are as many crabs. All these are by degrees removed from the ship, and are kept alive and ready for the market in the *carbs*—spacious perforated trunks made for the purpose.' Orkney and Shetland also yield a part of our lobster supply; and Mr T. E. Symonds, R.N., states in a pamphlet on the Irish fisheries, that 'in no country in the world are lobsters more numerous, or in greater perfection, than on the coast of Ireland, especially the west and north-west; and if the fishery was properly worked, and means devised for preventing the capture of the young, the supply would be sufficient for all the markets of the United Kingdom that now have recourse

to foreign sources. To shew the importance of this fish to the London market, large class well-boats are sent from thence, and other English ports, expressly for the purchase of lobsters, which they procure at the rate of from 4s. to 6s. per dozen, to almost any extent; 10,000 per week are readily obtained at these prices at several places on the west coast, and the number might be doubled if, by proper and stationary appliances, the country-people were saved the trouble of sending them to market. The average wholesale price in Billingsgate is 1s. each, or £50 per 1000; though sometimes, from gales, or contrary winds, or calms, they are scarce, and realise more than double that price in that and other markets. Under the present disadvantages of carriage to the rail by *car* and *sailing-boat*, there are very heavy losses in lobsters taken on the west coast, many hundreds dying on the journey, and consequently unsaleable; and others being deteriorated, sell at a very reduced rate. . . . The Irish fish are the finest, but the voyage being longer, is not so certain, and is attended with more risk, lobster carrying being subject to the following contingencies: thunder kills them when in the well, also proximity to the discharge of heavy ordnance. Mr Scovell lost several thousands from the latter, one of his smacks having anchored at night too near the saluting-battery at Plymouth. Calms also destroy the lobsters in the well, but onward or pitching motion in a sea-way does not affect them. They keep alive one month in the well without food. The above causes have no effect on lobsters in the pond. . . . Lobsters have been constantly brought from Norway to London in a screw well-boat—a passage of 500 or 600 miles—with very few casualties; whereas, in *sailing-vessels* there are many thousands lost continually. By a return from the Midland and Great Western Railway of Ireland, it appears that 101 tons 6 hundredweights of lobsters were carried from Galway on that line during the year ending 31st December 1854, in addition to those taken by well-boats to London by sea.'

The common edible crab is too well known to require description. The most remarkable feature in its economy, and which indeed is common to all crustaceans, is the process of sloughing, or moulting at regular periods the entire calcareous covering or crust. As it is obvious that the hard shell, when once perfected, cannot change with the growth of the animal, it becomes necessary that it should be shed entirely. When the season of shedding arrives, the aquatic crabs generally seek the sandy shores of creeks and rivers, and having selected a place of rest, the change begins. The body seems to swell; the larger upper shell begins to separate from the breast or corslet; the muscles of the limbs soften and contract, which allows of their slipping from their cases; the parts about the head and antennæ undergo a similar change; and gradually the animal escapes from the crust, soft, helpless, and incapable of exertion or resistance. In twenty or thirty hours, however, a thin crust has again overspread its various parts and members, and in the course of a few days it is enabled to resume its wonted habits. During the moulting season, as well as during the period of spawning, crabs are worthless; at other times they are excellent. On the rocky coasts they frequent, they are either drawn at ebb-tide from the holes and crevices, by means of an iron hook, or they are fished for, in four or five fathoms water, by traps or cages baited with garbage. Immense numbers are annually consumed in all our seaports.

Oysters are universally known and appreciated. The principal breeding-time is in the summer months, when their spawn is usually cast: this appears at first like spots of grease, which fasten upon rocks or other hard substances that happen to be near. Very commonly they adhere to adult shells, and thus are formed the large masses called oyster-banks. In about a year and a half, the young oysters have attained a profitable size, and are then dredged up and conveyed direct to market, or are transferred to artificial pits or beds within tide reach, where they are fattened to the desired size. Though this practice of transference has been carried on from the time of the Romans downwards, it has nothing to recommend it beyond convenience, and certainty of obtaining a regular supply; for the transplanted oysters, or *exiles*, according to connoisseurs, are never found in such perfection as *natives*. As with every other article of luxury, so with oysters: certain varieties are more fashionable and popular than others. In London, the Colchester and Milton oysters are held in most esteem; Edinburgh has her 'whiskered Pandores' or Cockenzie, and Newhaven and Prestonpans oysters; and Dublin the Carlingford and Powldoodies of Burran. Swansea is also famous for its oysters. The British trade in oysters is of very considerable importance, and ranks next to that in salmon, herrings, and white fish.

FURTHER DEVELOPMENT OF THE FOOD-FISHERIES.

No less than four joint-stock companies were projected in 1856, having for their object the greater development of our fisheries. These companies are to employ steamships, and are otherwise to be adapted to the extended commercial enterprise of the present day. The prospectus of one of these companies says most truly, that 'the wealth and energies of the United Kingdom are, in other channels, rapidly developing our great industrial resources; but our fisheries remain in the same state in which they were two centuries ago. Our increasing population requires that every means that art and science can devise should be adopted, in order to procure the necessaries of life as abundantly and cheaply as possible; but though it is well known that the seas which surround the British isles teem with abundance of fish, yet the supply of that article of food is always uncertain, and its price, generally high, is often exorbitant. The British fisheries, if conducted on a proper system, and on a scale of sufficient magnitude, are capable of yielding an abundant supply of wholesome food. There is no branch of our national industry to which steam-power can be more advantageously and profitably applied. Fishing-banks as yet untouched, because they could not be reached by the present sailing-craft employed in the trade, may, by means of steam-power, be made available for a vastly increased and more regular supply of fish. Hitherto, our fisheries have been prosecuted only by the coast fishermen in sailing-vessels at particular seasons; and the principal part of the fish caught has been cured for export, or sent to London, where the demand may be said to be almost unlimited. By the adoption of steam-power, the regular and daily supply of this article of food, in the freshest state, would be extended to the principal ports of the United Kingdom, to be thence conveyed by rail to the cities and towns of the interior.'

We are also glad to see that some of these companies intend to devote their energies wholly to the extension and encouragement of the fisheries on the Irish coasts, and also to those on the west coast of Scotland. It is said that 'the seas on the west coast of Scotland, and more particularly surrounding the Western Islands, are known to possess an inexhaustible mine of wealth. Not only do they contain "greater shoals of fish than those of any other country on the globe," but they now afford peculiar facilities for making these available. Unlike the east of Scotland, the west of Ireland, or almost any other line of coast where fishing is prosecuted, the west of Scotland, in its varied mainland, its endless indentations, and numberless islands, presents a line of coast capable of being fished, extending, on a moderate computation, to upwards of 4000 miles; while its peculiarities are such as to allow of fishing being carried on at any season of the year, and in almost any kind of weather; "for there," as Dr Anderson's Report truly says, "except on the west coast of Cantyre, no wind can blow that would not admit of entering a safe harbour to leeward."'

II. THE OIL-FISHERIES.

Gas, as a means of lighting both our houses and our cities, has to a great extent rendered us independent of the use of certain kinds of oil, but, nevertheless, the varieties of sea-animals and fish from which this valuable substance can be obtained, are still in demand. In addition to the Greenland and sperm-whale fishery, we have various other sources of supply. From the liver of the valuable cod-fish, we derive an oil which occupies an important place in this country as a medicine; and the sunfish, or basking-shark, is also valuable, principally from the value of its liver. The seal also is now prized both for the sake of its skin, and because it yields a large quantity of oil.

CETOLOGY.

Even the greatest of our naturalists have been puzzled in their attempts to elucidate the natural history of the whale; and although many books have been written on the subject, the real information conveyed in them is of little moment. As one of our chief writers expresses it, 'an impenetrable veil still covers our knowledge of the cetacea;' and the late Dr Scoresby himself, who had a personal knowledge of the subject, has told us that 'no branch of zoology is so much involved as that which is entitled cetology.' Very few of those authors who have written on the whale, ever saw a living member of the species; indeed, we cannot name over half-a-dozen writers who have had any personal acquaintance with these leviathans of the deep in their own element. The most reliable authors on the subject are, Scoresby on the Greenland fishery, and Messrs Beale and Bennet on the great sperm-whale; and it is principally from these authorities that all the popular information on the natural history of the whale has been derived.

The cetaceous order of animals, of which the whale is the most remarkable and important member, is distinguished by various peculiarities, which render it a link, as it were, between the creatures of the land and the sea. While living in part or wholly in the ocean, and so formed as to make their way through its waters with ease and velocity, the cetacea differ from the true fish-tribes in being *mammalian*, or suck-giving animals; in being warm-blooded; and in having organs for respiring the atmospheric air, like the ordinary inhabitants of the land. These striking distinctive features would be sufficient in themselves to render this order of animals an object of interesting study (see ZOOLOGY); but the cetacea have also strong claims upon attention, as being of very great consequence to the wants and comforts of man. This is especially the case as regards the members of the whale family (*Balænidæ*). As the characters of the Greenland whale (*B. mysticetus*) are mostly identical with those of the whole tribe, we will direct our attention to it and to the spermaceti, as being the types of construction in the principal members of the general family, which is very numerous, embracing as it does the Greenland or right whale, the great rorqual, the cachalot or spermaceti whale, the narwhal, bottle-nose, ca'ing, and others too numerous to specify; but varying in size from the dimensions of a large cod-fish, to a length of upwards of 100 feet, and a weight of nearly as many tons.

The Greenland Whale.—Very exaggerated notions at one time prevailed as to the size of the whale, some writers asserting that 160 feet was not an uncommon length. The late Dr Scoresby, however, declared that the common whale seldom or never exceeds seventy feet in length, and is much more frequently under sixty. Out of 322 whales which he had personally aided in capturing, *not one* exceeded fifty-eight feet; and the largest ever taken, of which he knew the reported measurement to be authentic, came up only to sixty-seven feet. The greatest girth is from thirty to forty feet, the thickest portion of the animal being immediately behind the head; the head occupies a space equal to a third of the whole body. The whale is destitute of the back or dorsal fin, but possesses two pectoral fins, which are situated about two feet behind the angles of the mouth, and are nearly five feet broad by nine feet in length. The tail, which is formed in the shape of a crescent, is horizontal, and about twenty-four feet broad. It is an instrument of immense power; and the whale has sometimes given a stroke with it which has sent large boats high into the air in a thousand splinters. The colour of the body is mainly a velvety black; the under part of the head and abdomen, and the junction of the tail, being partly white, and partly of a freckled gray. The eyes of the whale are about a foot behind the angle of the mouth, and are not much larger than those of the ox. The iris is of a white colour, and the organs are guarded by lids and lashes, as in quadrupeds. The two blow-holes of the whale, situated on the summit of the head, and descending perpendicularly through it for a length of twelve inches or so into the top of the windpipe, are the only other external features worthy of notice.

The mouth of the common whale is an organ of wonderful construction, and in a large specimen it may measure, when fully opened, sixteen feet long, twelve feet high, and ten feet wide. It contains no teeth; and enormous as the bulk of the creature is, its throat is so narrow that it would choke upon a morsel fitted for the deglutition of an ox. An inch and a half is stated to be the diameter of the gullet in the very largest whales. From this peculiarity of formation, it may be anticipated that the food of the animal is of a very minute nature, notwithstanding the vastness of the cavity which is prepared for its primary reception. The animal is indeed supported upon a multitude of smaller inhabitants of the deep; and to permit this, its mouth is provided with a remarkable apparatus, composed of what is called *baleen*, the well-known *whalebone* of commerce. The baleen is arranged in two rows of laminæ, or thin plates, projecting laterally from a line in the centre of the arch of the palate, somewhat like the laminæ of a feather. There are about 300 of these plates on each side; and when dried, they weigh usually above a ton. The longest plate, which is always placed about the centre of the series on each side, measures about twelve feet in length by fifteen inches in breadth. The use of these elastic plates, with their pendulous fringes, is to retain, as in a net, the multitude of small animals which are floated into the mouth of the whale whenever it is opened. Were it not for such a drainer, formed by these fringes with the aid of the tongue, which is merely a great mass of fat tied down to the lower jaw, the emission of the water would be attended by the escape of all the objects which entered with it. As it is, the most minute matters are retained; and shrimps, sea-snails, small crabs, medusæ, beröe, &c., are thus entrapped to support the great monster of the deep.

The skin of the whale consists, first of the scarf-skin or epidermis, which is moistened by an oily fluid, enabling it to resist the action of water; secondly, of the *rete mucosum*, a layer usually held to contain the colouring matter of all animal surfaces; and, thirdly, of the true skin, which, for particular purposes, is open in texture, so as to contain the blubber, from which the oil is boiled out in great quantities. This mass—which surrounds the whole animal in a layer from one to two feet thick, and sometimes weighs more than thirty tons in all—serves the important end of keeping the animal warm by its weak conducting powers, and is also calculated to resist the enormous pressure to which the body of the creature must be subjected at the depths to which it often descends. Moreover, being inferior in specific gravity to water, it is obvious that all this body of oil must be of the greatest service in augmenting the buoyancy of the animal's frame. Below the skin are situated the muscles or flesh, which is red in colour, and tastes like coarse beef; and the character of this structure is much the same in the whale as in the ox or

horse. With the exception of the tail, the arrangement of the various muscles of the whale does not differ very much from that of quadrupeds, and the same remark applies to the osseous structure. The fins are merely rudimental arms, containing nearly the same bones as in man, and the chest strongly resembles that of ordinary quadrupeds. The vertebral column of the rorqual whale contains sixty-three bones, those of the Greenland whale are not quite so numerous. The skull consists of the crown-bone, from which the facial bones and upper jaw project forward, while the lower jaw is composed of two long curved bones, that meet at the point or forepart of the mouth. The whole of these bones are hard and porous, and some of them contain large quantities of fine oil, but they have no proper medulla or marrow.

The organs of respiration in the whale are formed upon the same principle as those of land-animals, but with modifications to suit the element in which the creature lives. It is plain that some provision was required to permit the whale to breathe, without the risk of having the lungs filled with water. This is accomplished by the extension of the top of the wind-pipe into the nostrils or blow-holes, or rather into the passage which terminates in these in the common whale. By this contrivance, the creature can inhale air while it is feeding or has its mouth full of water. As with terrestrial animals, the air gives a red colour to the blood, or, in other words, oxygenates it, and sustains the animal heat. Accordingly, the whale has frequently to come to the surface for air; but this operation is rendered less frequently necessary by the provision of a reservoir, consisting of a plexus of vessels filled with oxygenated blood, which can be drawn upon when required. The quantity of the blood, too, is great in proportion to the whole mass of the frame. The brain of the whale is held by Cuvier to be large in relation to the animal, but the arrangements of its nervous system are not understood. It is known that whales possess pretty acute vision, but there is a doubt whether or not they have any external ear. Their sense of smell seems to lie in the blow-holes; yet the strongest reason for ascribing such a faculty to them at all is founded upon the half-traditionary notion of sailors, that if certain strong-smelling substances are thrown overboard, whales will fly from the spot at once. The mammæ of the common whale are two in number, and attached to the abdomen; in the case of some other varieties, they are placed on the breast. The milk of the animal is said to be rich and creamy.

The cachalot or spermaceti whale differs from the Greenland species in having no baleen. It is much larger in size than the right whale, being frequently found to extend to a length of seventy or eighty feet, and sometimes even attaining the extraordinary dimensions of ninety and a hundred feet, from the snout to the tail. Some species of the spermaceti whale possess two, others three fins; some have the spout in the neck, others in the snout; some have flat teeth, and others sharp teeth; and the colour of the back varies between black, blue, and gray. Generally speaking, the characters now to be noticed are proper to all. The head is enormous in bulk, being fully more than a third of the whole body, and it ends like an abrupt and steep promontory in front. On the upper part of the snout is placed the blow-hole, often verging a little to one side; and it is a remarkable fact, that this is but one of the various deformities, whether congenital or acquired in the terrible battles waged by the creatures with one another, which are commonly found on the body of this whale. Its eyes are unequal, and the left frequently useless. The back has a greenish-gray tint, and below, much of the creature is white. On the back there are in most of the species one or two small fins, with large protuberances; the side fins are also of small size; but the tail is an instrument of amazing power. The teeth are usually about forty-two in number, and fit into depressions in the upper jaw. In this whale, the gullet is wide enough to admit a man, and the animal feeds on large fish. A cephalopodous mollusk (*Sepia octopus*), called *squid* by the sailors, is its chief food in deep seas.

The size of head in the sperm-whale has a very extraordinary purpose to serve. To assist in floating the animal, a great cavity in the interior of the skull is filled with a fine oil, which becomes concrete on cooling, and forms the spermaceti of commerce. Some of this oil is also found along the vertebral column; and in a bag in the intestines another valuable substance lies, the ambergris of traders. These are the principal objects of the sperm-whale fishery, the blubber procured from this variety of the cetacea not being nearly so abundant as in the case of the mysticetus. At the same time, the blubber of the sperm-whale is valuable, and is converted into sperm-oil. The sailors know this whale, at a great distance, by the act of blowing, which it performs with great regularity, at intervals of ten minutes or so. The spout sent up is visible at a distance of two or three miles, and has the appearance of a misty cloud or bush. Having thus blown sixty or seventy times, and made inspirations as often, the animal descends, and can remain under water more than an hour, subsisting on the store of blood which has been oxygenated, and is kept in the reservoirs already described. This alternation of appearances and disappearances is gone through by the animal with undeviating regularity, unless it be disturbed. The sperm-whale is timid before man, yet it fights fiercely with those of its own race. Fights usually take place when male whales, or *bulls*, as they are called, and one or two of which always attend a particular herd of females, meet with rivals desirous of entering their company. They lock jaws with one another, and exert a dreadful degree of power at one another's cost. When alarmed, or harpooned, they sometimes roll over and over on the surface of the water in an amazing manner. Still, they are not furious or dangerous towards the mariner, but are commonly killed with ease. The sailors call a herd a *school*, and the old bulls the *schoolmasters*. The females are said to be smaller than the males by a fourth. They are, like the Greenland whale, very fond of their young, and also of one another; so much so, that by cautious management, a whole herd may be destroyed, as they will scarcely quit a wounded companion.

The mode of killing these leviathans of the deep is almost always the same, and whether they are Greenland or sperm whales, the harpoon is the instrument commonly used for their destruction. Various new methods for killing the whale have been tried—such as a mortar to project shells into them, also a gun from which to fire the harpoon—but these methods have not been attended with much success.

THE SPERMACETI-WHALE FISHERY.

Some years ago, very little was known either about the natural history of the sperm-whale, or of the great value of its products to mankind. It was only when one of these mighty animals happened to be stranded, that its oil was obtained; and the valuable spermaceti, one of its products, was popularly supposed to be derived from a different source. In those days, this substance was of course exceedingly scarce, and only to be purchased at druggists' shops as an ointment or medicine. In course of time, the value of the animal came to be discovered, its haunts were eagerly sought out, fleets of ships set off to explore, and its pursuit and capture soon became a valuable source of gain, especially to the enterprising sailors of the American merchant-service.

The cachalot is certainly the largest inhabitant of the mighty deep, the most valuable to man, and the most formidable to do battle with. The substances derived

from this leviathan of the seas, are sperm-oil, spermaceti, and occasionally ambergris, which is found concealed in a bag in its intestines, or is, as some writers assert, the fœces of the animal. The South-sea whalers are vessels of about 400 tons, and are smart, well-rigged ships, manned by expert seamen, who are paid by a share of the proceeds of the fishery. They provide for a long cruise: it lasts, on the average, from three to four years; and they differ in many respects from the Greenland ships, as they carry a furnace and boilers, called *trypots*, for the purpose of extracting the oil as soon as a fish is captured. The crew averages from about thirty to forty people, including the master, surgeon, mates, harpooners, &c. The best possible arrangements are made for the health of the crew, and the vessel is always kept as clean as the nature of the business carried on will admit. Five boats are usually attached to the whaler, provided with every requisite; chief among which is the whale-line, made of fine manilla hemp, two-thirds of an inch thick. In speaking of this important part of the arrangement of a whale-ship, Herman Melville, a practical authority, says: 'In length, the common sperm-whale line measures something over 200 fathoms. Towards the stern of the boat, it is spirally coiled away in the tub, so as to form one round cheese-shaped mass of densely bedded sheaves, or layers of concentric spiralisations, without any hollow but the "heart," or minute vertical tube formed at the axis of the cheese. As the least tangle or kink in the coiling would, in running out, infallibly take somebody's arm, leg, or entire body off, the utmost precaution is used in stowing the line in its tub. Some harpooners will consume almost an entire morning in this business, carrying the line high aloft, and then reeving it downwards through a block towards the tub, so as, in the act of coiling, to free it from all possible wrinkles and twists.'

The great hunting-field for the sperm-whale is the vast Pacific Ocean. When the ship arrives on likely 'ground,' a sharp look-out is kept both for single whales and the *school*, or shoal, often to be seen led by one or two of the larger males or 'bulls.' The sperm-whales are in ordinary circumstances shy, and it requires much caution before those in pursuit can come so near a single fish as to fix it with a harpoon. They have the power of raising their heads perpendicularly out of the water to a very considerable height; and when in this attitude, which seems to be assumed for the purpose of viewing the surrounding expanse, they present the appearance of huge black rocks. They are said to have the ability, also, on noticing any object, to communicate the intelligence to their companions, though the manner in which this is done remains a secret. Mr Beale gives it as his opinion, that the sperm-whale can communicate signals to a distance of four, five, and even seven miles. This cannot be effected by sounds, for, above water at least, the animal utters no noise whatever, if we except the hissing sound accompanying the act of respiration. With regard to its other habits, the sperm-whale much resembles the Greenland whale. It is often seen, like its northern congener, to leap directly out of the water, or to *breach*, as the sailors call the action. Its purpose is to get rid of various sucking fish and crabs, which are fond of effecting a lodgment upon its mountainous body, and which often remain there till plucked from off the captured animal by the whalers. Successive watchers are stationed upon each mast-head to keep a look-out—not in a crow's-nest, like the Greenland whaler, but simply on the cross-trees, as the South-sea ships are not provided with a crow's-nest. When the magic 'There she spouts!' is sounded by the look-out, the crew start at once into a state of the greatest excitement. The boats are instantly lowered; the crew rapidly take their places, and away they pull, straining every nerve to come up with the huge leviathan before it dives. Arrived within reach of the animal, the command is given: 'Stand up, and give it to him.' The harpooner, dropping his oar, seizes his iron dart, and poising it high above his head, with unerring aim hurls it deep into the flesh of the gigantic cachalot. 'Stern all!' is now the cry, and the boat is backed out of reach of the stricken whale, while all the time the *line* is hissing over the gunwale with fierce velocity. The line runs out all its length; the boat, dragged by the whale, flies through the water, 'like a shark all fins.' As a whaleman says, 'whole Atlantics and Pacifics seem passed as they shoot on their way.' At length the line slackens, and the crew proceed to haul it in till the boat once again comes up with the whale, when dart after dart is hurled into the quivering body of the fish, the boat all the time, as a spectator has described the scene, 'alternately sterning out of the way of the whale's horrible wallow, and then running up for another fling. At length, tormented and wounded to death, the gigantic whale gets into that state known as the *flurry*, which may be described as the last dying flicker of the candle. After being "overwrapped in impenetrable and boiling spray, the whale once more rolls out into view," surging from side to side; spasmodically dilating and contracting his spout-hole, with sharp, cracking, agonised respirations. At last, gush after gush of clotted red gore, as if it had been the purple lees of red wine, shot into the frighted air; and falling back again, ran dripping down his motionless flanks into the sea.'

The next business is to tow the large carcass to the ship, where it is cut up and the blubber boiled for the purpose of extracting the oil. It is first firmly lashed to the side of the vessel, or suspended by appropriate gear from her rigging. The work of *flensing*, or cutting off the blubber or fat, must be expeditiously performed, for the hungry sharks, smelling the blood from afar, quickly surround the dead mass, anxious to obtain a meal. Thousands of these devouring monsters congregate round the ship, and in a few hours the valuable mass would be reduced to a heap of bones, were it not speedily cut into strips, and carried on board. This process is performed by the crew, who are armed with sharp-cutting spades made for the purpose. A great mass is first cut away, and then hauled on board by means of a block and tackle. The head is got into the ship in one great mass, and then comes the command: 'Haul in the chains—let go the carcass.' 'The vast tackles,' says Melville, 'have now done their duty. The peeled white body of the beheaded whale, flashes like a marble sepulchre; though changed in hue, it has not perceptibly lost anything in bulk. It is still colossal. Slowly it floats more and more away, the water round it torn and splashed by the insatiate sharks, and the air above vexed with rapacious flights of screaming fowls, whose beaks are like so many insulting poniards in the whale. The vast white, headless phantom floats further and further from the ship, and every rod that it so floats, what seem square roods of sharks and cubic roods of fowls, augment the murderous din. For hours and hours, from the almost stationary ship, that hideous sight is seen. Beneath the unclouded and mild azure sky, upon the fair face of the pleasant sea, wafted by the joyous breezes, that great mass of death floats on and on till lost in infinite perspectives.'

The spermaceti is now extracted from the head, and the preparation of the oil commences. Once kindled, the furnace gives out an intense heat, which is kept up by throwing in all the refuse matter. The apparatus for boiling is called the *try-works*, and the operation of boiling the blubber is termed *trying-out*. The harpooners, 'with huge pronged forks, pitch the hissing masses of blubber into the scalding pots, or stir up the fire beneath, till the smoky flames dart curling out of the doors to catch them by the feet. Anon the smoke rolls away in sullen heaps. To every pitch of the ship there is a pitch of the boiling oil, which

seems all eagerness to leap from the copper.' After this process, the oil is conveyed to the coolers; and, finally, it is run into the barrels or tanks; and on some fine day, the battered ship, after an absence of perhaps four years, runs to her port, and so finishes her adventures for the time.

The cachalot is seldom seen in the Greenland seas. It is spread, however, over an immense expanse of the ocean, having been captured almost everywhere between the latitude of 60° south and 60° north. The coasts of New Guinea and the adjacent archipelagoes, the shores of New Holland, Mitchell's Group, New Zealand, Navigator Isles, Ellis's Group, the shores of Peru, Chile, California, Japan, the Persian Gulf, the Chinese seas, the Moluccas, and many other regions of the ocean, abound more or less with this valuable cetaceous species.

As in the case of the Greenland fishery, bounties were given to the sperm-whalers up to 1821, when the trade was fairly left to private enterprise. In 1791, the sperm-oil imported into Britain amounted to 1258 tuns; in 1827, 5552 tuns were imported; and in 1836, the amount was 7001 tuns. One good whale will yield forty barrels of oil, and ten barrels of spermaceti are frequently taken from one head. About ten large barrels make a tun. Both sperm-oil and spermaceti bear a high price in the market, and are of great utility in various respects. Of late years, this branch of the oil-fishery has also fallen off; so much so, that in 1845 not a single vessel cleared out for it from a British port. 'This decline,' says M'Culloch, 'is a consequence partly of the growing scarcity of the whales in their old haunts, and of the greater difficulty experienced in their capture; but more of the competition of the Americans, and of the colonists in New South Wales and Van Diemen's Land. The situation of the latter gives them peculiar advantages for the prosecution of the fishery, which they now carry on to a great extent, and with much spirit and success.' In 1841, there were no fewer than 193,000 tons of shipping belonging to the United States engaged in sperm-fishing; and although it is difficult to obtain accurate statistics on the subject, it is supposed that even now, when the fish are scarcer than ever, the amount of shipping engaged in the South-sea fishery has not fallen off, but, on the contrary, has increased.

RISE AND PROGRESS OF THE NORTHERN SEA WHALE-FISHERY.

It is natural to suppose that those nations dwelling on the shores of the arctic seas would be the earliest engaged in the whale-fishery; and accordingly we find that not only did the Norwegians and other Scandinavians precede all the other nations of Europe in this perilous but profitable line of enterprise, but they also were the first introducers of it among the southern nations. The shores of the Bay of Biscay, where the Normans formed early settlements, became famous, through them, for the whale-fishing there carried on. In the same region was it first made a regular commercial pursuit, and as whales then visited the bay in great quantities, the traffic was convenient and easy. The Biscayans maintained it with great vigour and success in the twelfth, thirteenth, and fourteenth centuries. We find from the work of Noel, *Upon the Antiquity of Whale-fishing*, that in 1261, a tithe was laid upon the tongues of whales imported into Bayonne, they being then a highly esteemed species of food. In 1338, Edward III. relinquished to Peter de Puyanne a duty of £6 on each whale, levied on those brought into the port of Biarritz, to indemnify him for the extraordinary expenses he had incurred in fitting out a fleet for the service of his majesty. The Biscayans, however, soon gave up the whale-fishing, from the want of fish, which ceased to come southward, no longer leaving the icy seas. The voyages of the Dutch and English to the Northern Ocean, in order to discover a passage through it to India, though they failed in their primary object, laid open the remote haunts of the whale. The British Muscovy Company obtained a royal charter, prohibiting all vessels but theirs from fishing in the seas round Spitzbergen, under pretence that it was discovered by Sir Hugh Willoughby. The fact, however, was, that Barentz, a merchant-seaman of Amsterdam, had discovered it in 1596; and neither Dutch, Spaniards, nor Frenchmen were at all disposed to admit the justice or propriety of the claim made by the English. An extraordinary scene followed in the northern seas. The Muscovy Company sent out six or seven strongly armed vessels, which took up a position near Spitzbergen, and commenced an attack on all foreign ships that refused either to quit the region at once, or pay the very moderate toll of one-half the proceeds of their fishing! The English succeeded so far as to annoy everybody else, and to prevent themselves from taking almost a single fish, so busy were they in looking after others. All the nations of Europe remonstrated loudly through their envoys against these proceedings; but the Dutch, ever fearless at sea, sent out a strong fleet, which effectually guarded their own fishing. At length, in 1618, a general engagement took place, in which the English were worsted. Hitherto, the two governments had allowed the fishing adventurers to fight out their own battles; but in consequence of the event mentioned, it was considered prudent to divide the Spitzbergen bays and seas into fishing-stations, where the companies might not trouble each other. After this period, the Dutch quickly gained a superiority over their rivals. While the English prosecuted the trade sluggishly, and with incompetent means, the Dutch turned their fisheries to great account, and in 1680 had about 260 ships and 14,000 sailors employed in them. We are told in a little work which contains some statistics of the whale-fishery, that in the year 1697, 188 vessels, fishing in one bay, had on board the produce of 1959 whales.

After the cessation of the Muscovy Company, a Greenland Company, with an actual capital of £45,000, entered on the trade, and in nine years came to a ruinous close. In 1725, the South-sea Company took up the adventure; and in eight years, after a vast outlay, they also were compelled to submit to a dead loss of their capital, and throw up the attempt. The legislature now tried a new scheme, being sincerely desirous to encourage and establish the trade, as well as to make it a nursery for seamen. In 1732, a bounty of 30s. a ton was granted to every ship of 200 tons burden that engaged in the fishing. In 1749, it was thought necessary to raise the bounty to 40s., when, as Mr M'Culloch observes, as many ships seem to have been fitted out for catching the bounty as for catching fish. But a trade supported on any other principle than that of direct benefit received from it by the parties engaged therein, can never be of an enduring nature, and this truth soon appeared in the present case. In 1777, the bounty was reduced to 30s., the consequence of which was, that during the next five years, the number of ships employed in the trade was reduced from 105 to 39! In 1781, the bounty was raised again to its old level, and an inducement was thus held out for the revival of the spirit of trade. But after all, what a million and a half of money, expended in successive donations under the name of bounty, was totally insufficient to do, the spirit of private enterprise, once fairly awakened, speedily accomplished. The British whale-fisheries throve rapidly between 1781 and 1795; and the legislature found themselves justified in reducing the bounty, at intervals, from 40s. to 20s. In any sketch of the whale-fishery, Peterhead deserves especial mention. The Peterhead Greenland fishing commenced in 1788, and for fourteen years afterwards, one vessel per annum regularly left the port in pursuit of the

whale. In the first eight years, the produce was only six fish; but in 1798, greater enterprise began to be manifested, and some voyages produced as many as eleven whales. For many years, a considerable number of ships have left this flourishing port. In 1852, the number was 22; in 1855, 27; in 1856, 28, and in 1857, 30; some of those, however, were engaged in the seal-fishery. The provisioning alone of the fleet which left in 1857, cost nearly £16,500. The long continental troubles consequent on the French Revolution, put a complete period almost to the Dutch fishing, while in the same space of time the British fisheries were continually improving, the conduct of them being left entirely to the private spirit of the nation. A small bounty, indeed, was given even down till 1824; but it was uninfluential, and was then withdrawn altogether.

THE DAVIS' STRAIT FISHERY.

Captain Penny, the well-known whaler, informs us that the cause of the failure of the whale-fishery in Davis' Strait, is not so much from the scarcity of whales, as from the want of a proper knowledge of their habits. In former years, the whales used to be found in great abundance in north latitude 62½°, longitude 60°, at the edge of the pack. On this bank, a little north of the entrance of Hudson's Strait, they were at one time very numerous, but being so much harassed by ships, they have now almost entirely deserted this haunt. The next fishing spot frequented by the whalers was South-east Bay, in latitude 69°, longitude 55°, where whales were likewise found in great abundance; but in consequence of so many ships frequenting the place, they have also in a great measure deserted this locality; and were then followed as far north as North-east Bay, between latitude 71° and 72°, longitude 50°—the highest latitude visited by the whalers on the east side of the Strait. Of late years, however, few vessels having frequented Davis' Strait, the whales have again commenced visits to their old haunts. The above fishing-banks are those generally frequented by the whaling-vessels, from the middle of April until about the 4th of June, when the vessels proceed between the body of ice which lines the American shore in the land-water, towing, tracking, and warping* until they round the ice by Cary Islands, in latitude about 77° (a distance of 700 miles), to the next whale-fishing bank, Pound's Bay, on the American shore; and if they reach this from the end of June till about the 7th of August, when the whales are found playing by the edge of the fixed ice, a most successful fishing is generally the result.

After this period, the whale dips under the edge of the ice, and proceeds into the inlets which have become free in consequence of the great warmth which the land has now acquired. In these bays and inlets, the whales repose in perfect security, being unapproachable by whale-fishing ships. Perhaps one or two may be taken, if any of the more energetic tribes of Esquimaux happen to reside in their neighbourhood. But if a track of south-west winds set in, keeping the ice packed into the strait, preventing the ships from approaching their haunts, the fishery is then a partial failure, and the vessels have to fish down along the American shore, watching the time when the whales again take their course along the land to the south, which they generally do from the 1st of September till the 10th of October. The whales then have recourse to the deeply indented inlets of Cumberland Sound and Frobisher's Straits, feeding and playing in perfect security amongst the thousand islands, dangerous shoals, and rapid tides. The fish resort to these inlets to calve. They are sometimes to be seen in immense numbers sporting in the most frolicsome manner; and at other times, the enormous fish of 65 feet in length by 30 in breadth, with a tail 28 feet broad, leaps out of the water like a salmon, causing the spray to rise to a great distance. On these occasions, they are very watchful, and cannot be approached but with the greatest caution—the male whale making a circuit round the female to see that no enemy is approaching.

The great difficulty in the whale-fishery is to get to their haunts in season, and the only proper method of doing so is to winter beyond the barrier of ice, which extends over a breadth of 250 miles. This method has now been successfully accomplished by harbouring in a position so that the edge of the land-ice may be reached by means of sledges and dogs in the month of M[ay] with the assistance of the natives.

The Greenland Fishery has almost been a failu[re] for the last twenty years. Occasionally there are so[me] successful voyages; but the whales have been so mu[ch] harassed that they have taken shelter in the Arct[ic] Ocean, beyond those barriers of ice which lie betwe[en] Old Greenland and Spitzbergen, and between No[va] Zembla and Spitzbergen. Captain Penny, to who[m] we are indebted for much of our information on t[he] whale-fishery, says: 'There is no doubt but that beyo[nd] these barriers there is a large Arctic Ocean, which abo[ut] midsummer may extend to the north pole. And I fe[el] assured that Britain's sons, with the aid of scre[w] steamers, will yet reach, by Nova Zembla route, the ve[ry] gates of the Pacific, and return in one season wi[th] valuable cargoes of whales, where I suppose them [to] exist in thousands, reposing as yet in perfect securi[ty] from the art of man.' It is unnecessary to enter in[to] the mode of capturing the Greenland whale, as it [is] essentially the same as that of the sperm-whale alrea[dy] described.

The greatest cargo ever borne to the shores of Britai[n] by a whaling-vessel was that brought from Spitzberge[n] by Captain Souter of the *Resolution* of Peterhead, i[n] the year 1814. It consisted of 44 whales, which pr[o]duced 299 tuns of oil; value—reckoned at £32 per tu[n] the average price of that year—£9568; and whe[n] to this sum is added the value of the whalebone, an[d] the bounty, the whole would appear to have reache[d] £11,000. When oil rose to £60 per tun, smaller cargoe[s] in several instances, amounted to an equal value. I[n] 1813, the Scoresbys, father and son, respectively brough[t] home cargoes which produced £11,000. Captai[n] Scoresby, senior, in the course of twenty-eight voyage[s] captured the immense number of 498 whales, the o[il] and whalebone of which amounted in value to abo[ve] £150,000. It may be mentioned, that since the time [of] the Scoresbys, Captain Penny has adopted the practi[ce] of wintering on the station, and so making a goo[d] fishing. Thus, with his two vessels, the *Lady Frankli[n]* and *Sophia*, in 1853-4, he took forty whales, and abo[ut] 6000 seals; and the total value of his cargo reache[d] £20,000. The value of one of these monsters of th[e] deep may be considered—if a full-sized fish—to b[e] upwards of £700 or £800. The yield of oil is variable yet a good fish will give twelve to fourteen tuns, at £5[0] per tun, and one ton of whalebone, at £300 per ton which is no unprofitable concern to the owners, as well [as] to all on board.

Whale-oil is sold by the tun of 252 gallons win[e] measure, and its value fluctuates very much. Th[e] whalebone, which is next in value to the oil, is foun[d] in the mouth of the common Greenland whale. 'Whal[e]bone,' says Captain Scoresby, 'is generally brough[t] from Greenland in the same state as when taken fro[m] the fish. It is then subjected to a thorough cleansin[g] and after passing through a series of preparations, [is] ready for sale. Of late years, the price has been ve[ry] fluctuating.'

* *Tracking* is performed by the crew, who walk along the edge of the ice, and tow the ship after them: *warping* is effected by fixing the ice-anchor in a strong part of the ice several hundred fathoms ahead, when the crew on board pull the vessel towards it.

The following are the most recent statistics of the Greenland and Davis' Strait whale and seal fisheries, taken from the well-known circular of the Messrs Laurance of Peterhead:

TOTAL PRODUCE OF FISHINGS FOR EIGHT YEARS—1849-56.				
Place.	Seals.	Whales.	Tuns of Oil.	Cwts. of Bone.
Peterhead,	577,117	187	9,700	2,446

As indicating the energy of the American character in the pursuit of commerce, we subjoin here a document which will illustrate the part that country takes in the Arctic whale-fishery. It is by the secretary of the United States navy:

'NAVY DEPARTMENT, *April 5*, 1852.

'In the summer of 1848, Captain Roys, of the whale-ship *Superior*, penetrated the Arctic Ocean, through Behring's Strait, and encountered in his adventurous pursuit all the dangers of an unknown and Polar Sea. He was successful in his enterprise, filling his ship with oil in a few weeks. Influenced by the report which he brought back as to the abundance of whales, owners in the United States fitted out a large fleet for these grounds; and in 1849, Captain Roys was followed by 154 sail of whale-ships, each vessel (said to be) worth on the average, with her outfit, 30,000 dollars, and manned by thirty able-bodied seamen each. This fleet took that season 206,850 barrels of whale-oil, and 2,481,600 pounds of bone. In the summer of 1850, there went up a whaling-fleet of 144 American vessels, manned as above, and of a like average value. This fleet, in the course of the few weeks left for their pursuits in those inhospitable regions, took 243,680 barrels of whale-oil, and 3,654,000 pounds of bone. . . . . The lives and property at stake there for the two years for which we have complete returns, may be thus stated:

		Dollars.	Dollars.
1849. Number of American Seamen,	4650		
Value of Ships and Outfits, . . .		4,650,000	
" " Oil taken, ...		2,606,510	
" " Bone, ...		814,112	
			8,070,622
1850. Number of American Seamen,	4320		
Value of Ships and Outfits, . . .		4,320,000	
" " Oil taken, ...		3,761,201	
" " Bone, ...		1,260,630	
			9,341,831
Total Ships in Two Years, . . .		299	
Total Seamen, ...	8970		
Value of Ships and Cargoes, ...			17,412,453

* * * *

THE SEAL-FISHERY.

Those ships that cannot obtain 'fish,' very gladly kill as many seals as possible. This branch of enterprise seems to have been originally undertaken more from sport than any other motive. The first capture of seals as a matter of commerce, of which we have an authentic account, was in 1803, when Captain Geary of the *Robert* brought home 180 along with his seven whales. Almost incredible numbers are now caught; ships have been known to bring home as many as 15,000: from 2000 to 5000 is a common number.

The vessels employed in the seal-fishery usually leave this country about the 25th of February. They are generally delayed at Lerwick (Shetland Isles) until about the 5th of March, where they engage the greater number of their crew. Seals are found in great numbers in the Greenland seas; but the principal place for hunting them is at Spitzbergen, where numerous herds of them are to be found both on the ice and on the land. They are easily wounded by means of a spear, but they are difficult to kill, and are sometimes deprived of their skin before life becomes extinct. They are chiefly valuable for their skins, and their blubber, which is cut up into small pieces and conveyed home in barrels, yields a pure and valuable oil. The statistics already given, indicate the money-value of the seal-fishery.

MISCELLANEOUS OIL-FISHERIES.

In addition to the whale and seal, oil is obtained in considerable quantities from the great sunfish or basking-shark. Considerable numbers of this fish are to be found on our coasts, and the liver of each, from which the oil is extracted, is valued at about £30.

Cod-liver oil is now well known in *materia medica* under the name of *oleum jecoris aselli*. The best is made without boiling, by applying to the livers a slight degree of heat, straining through thin flannel or similar texture. When carefully prepared, it is quite pure, nearly inodorous, and of a crystalline transparency. The specific gravity at temperature 64° is about ·920. It seems to have been first used medicinally by Dr Percival in 1782 for the cure of chronic rheumatism; afterwards by Dr Bardsley in 1807. It has now become a popular remedy in all the slow-wasting diseases, particularly in scrofulous affections of the joints and bones, and in consumption of the lungs. The result of an extended trial of this medicine in the hospital at London for the treatment of consumptive patients, shews that about 70 per cent. gain strength and weight, and improve in health, while taking the cod-liver oil; and this good effect with a great many is permanent. *Skate-liver oil* is also coming into use for medicinal purposes.

PRESERVATION OF HEALTH.

A HUMAN being, supposing him to be soundly constituted at first, will continue in health till he reaches old age, provided that certain conditions are observed, and no injurious accident shall befall. This is a proposition so well supported by extensive observation of facts, that it may be regarded as an established maxim. It becomes, therefore, important to ascertain what are the conditions essential to health, that, by their observance, we may preserve for ourselves what is justly esteemed as the greatest of earthly blessings, and dwell for our naturally appointed time upon the earth. A general acquaintance with these conditions may be easily attained by all, and to render them obedience is much more within the power of individuals than is commonly supposed.

The leading conditions essential to health are—1. A constant supply of pure air; 2. A sufficiency of nourishing food, rightly taken; 3. Cleanliness; 4. A sufficiency of exercise to the various organs of the system; 5. A proper temperature; 6. A sufficiency of cheerful and innocent enjoyments; and 7. Exemption from harassing cares. These conditions we shall now treat in succession, taking as our guides the most recent and eminent of physiological authorities.

AIR.

The common air is a fluid composed mainly of two gases, in certain proportions—namely, 20 parts of oxygen and 80 of nitrogen in 100, with a very minute addition of carbonic acid gas. (See CHEMISTRY, p. 295.) Such is air in its pure and normal state, and such is the state in which we require it for respiration. When it is loaded with any admixture of a different kind, or its natural proportions are in anyway deranged, it cannot be breathed without producing injurious results. We also require what is apt to appear a large quantity of this element of healthy existence. The lungs of a healthy full-grown man will inhale the bulk of twenty cubic inches at every inspiration, and he will use no less than fifty-seven hogsheads in twenty-four hours. And not only is this large quantity necessary, but the air that surrounds us must be in free circulation, in order that what we expire may be speedily carried away, and allowed to commingle with the atmosphere, which is subject to never-ceasing causes tending to its restoration and renewal.

Now, there are various circumstances which tend to surround us at times with vitiated air, and which must accordingly be guarded against. That first calling for attention is the miasma or noxious quality imparted to the atmosphere in certain districts by stagnant water and decaying vegetable matter. It is now generally acknowledged that this noxious quality is, in reality, a subtile poison, which acts on the human system through the medium of the lungs, producing fevers and other epidemics. A noted instance of its thus acting on a great scale is presented in the Campagna di Roma, where a large surface is retained in a marshy state. The exhalations arising from that territory at certain seasons of the year, oblige the inhabitants of the adjacent districts of the city to desert their homes, and escape their pernicious influence. All marshes, and low damp grounds of every kind, produce more or less miasma; and it is consequently dangerous to live upon or near them. Slightly elevated ground, with a free exposure to light and air, should, accordingly, in all cases be chosen for the sites of both single houses and towns. Tanks and collections of water of every kind are dangerous beneath or near a house, because, unless their contents be constantly in a state of change, which is rarely the case, their tendency is to send up exhalations of a noxious kind. Some years ago, Viscount Milton—a youth of great promise, and who had recently become a husband and father—died of a fever which was traced to the opening of an old reservoir of water underneath the country-house in which he dwelt. A similar, but more extensively fatal tragedy took place at a farmhouse in the south of Scotland. Not only did the farmer, his wife, and a female servant sink under a malignant fever, but a son and daughter, and several other servants, narrowly escaped with their lives, and only by removing from the house. It was observed in this case that removal produced instantaneous improvement of health, but a return to the devoted dwelling at once renewed the ailment. On proper investigation, it was found that immediately behind the house was a kind of millpond, into which every kind of refuse was thrown, or allowed to discharge itself; and that this collection of putrid matter had not been once cleared out for a long series of years, no one dreaming of any harm from it. The momentous consequences from a cause so trifling, and the consideration that they might have been warded off by only a little knowledge of natural causes, furnish melancholy matter for reflection. Many analogous cases, which might be referred to, demonstrate that we are yet but in the infancy of an understanding of the subject of aërial poisons.

Putrid matter of all kinds is another conspicuous source of noxious effluvia. The filth collected in ill-regulated towns—ill-managed drains—collections of decaying animal substances placed too near or within private dwellings—are notable for their effects in vitiating the atmosphere and generating disease in those exposed to them. (See No. 30.) In this case also it is a poison, diffused abroad through the air, which acts so injuriously on the human frame. This was probably the main cause of the plagues which devastated European cities during the middle ages. In those days there were no adequate provisions for public cleaning, and the consequence was, that masses of filth were suffered to accumulate. The noxious air diffused by these means through the narrow streets and confined dwellings would tend to the most fatal effects. In old drains there is generated a gas—sulphuretted hydrogen—which is calculated to produce dreadful consequences in those exposed to its inhalation. It has lately been discovered that it is the presence of this gas, arising from the shores, river deltas, and mangrove jungle of tropical Africa, which causes the peculiar unhealthiness of that region. It is ascertained that small animals, such as birds, die when the air they breathe contains one-fifteen-hundredth part of sulphuretted hydrogen, and that an infusion six times greater will kill a horse. It follows that we can scarcely attach too much importance to measures for cleaning and improving the sewerage of cities. There are as yet no large towns in Britain kept in a state so clean as is desirable for the welfare of their inhabitants; nor will they be so till the measures now in agitation for improved modes of construction, for adequate supplies of pure water, and for thorough scavengering and sewerage, be adopted.

The human subject tends to vitiate the atmosphere for itself, by the effect which it produces on the air which is breathed. Our breath, when we draw it in, consists of the ingredients formerly mentioned, but it is

in a very different state when we part with it. On passing into our lungs, the oxygen, forming the lesser ingredient, enters into combination with the carbon of the venous blood—or blood which has already performed its round through the body: in this process about two-fifths of the oxygen is abstracted and sent into the blood, only the remaining three-fifths being expired along with the nitrogen nearly as it was before. In place of the oxygen consumed, there is expired an equal volume of carbonic acid gas, such gas being a result of the process of combination just alluded to. Now, carbonic acid gas, in a larger proportion than that in which it is found in the atmosphere, is noxious. The volume of it expired by the lungs, if free to mingle with the air at large, will do no harm; but if breathed out into a close room, it will render the air unfit for being again breathed. Suppose an individual to be shut up in an air-tight box; each breath he emits throws a certain quantity of carbonic acid gas into the air filling the box; the air is thus vitiated, and every successive inspiration is composed of worse and worse materials, till at length the oxygen is so much exhausted, that it is insufficient for the support of life. He would then be sensible of a great difficulty in breathing, and in a little time longer he would die.

Most rooms in which human beings live are not strictly close. The chimney and the chinks of the door and windows generally allow of a communication to a certain extent with the outer air, so that it rarely happens that great immediate inconvenience is experienced in ordinary apartments from want of fresh air. But it is at the same time quite certain that in all ordinary apartments where human beings are assembled, the air unavoidably becomes *considerably vitiated;* for in such a situation there cannot be a sufficiently ready or copious supply of oxygen to make up for that which has been consumed, and the carbonic acid gas will be constantly accumulating. This is particularly the case in bed-chambers, and in theatres, assembly-rooms, churches, and schools. An extreme case was that of the celebrated Black Hole of Calcutta, where 146 persons were confined for a night in a room eighteen feet square with two small windows. Here the oxygen, scarcely sufficient for the healthy supply of one person, was called upon to support a large number. The unfortunate prisoners found themselves in a state of unheard-of suffering; and in the morning all were dead but twenty-three, some of whom afterwards sunk under putrid fever, brought on by breathing so long a tainted atmosphere.

Although the vitiation of the air in ordinary apartments and places of public assembly does not generally excite much attention, it nevertheless exercises a certain unfavourable influence on health in all the degrees in which it exists. Perhaps it is in bedrooms that most harm is done. These are generally smaller than other rooms, and they are usually kept close during the whole night. The result of sleeping in such a room is very injurious. A common fire, from the draught which it produces, is very serviceable in ventilating rooms, but it is at best a defective means of doing so. The draught which it creates generally sweeps along near the floor between the door and the fire, leaving all above the level of the chimney-piece unpurified. Yet scarcely any other arrangement is anywhere made for the purpose of changing the air in ordinary apartments. To open the window is a plan occasionally resorted to, but it is not always agreeable in our climate, and sometimes it produces bad consequences of a different kind.

A plan, to a considerable extent serviceable, though not perfect, for producing a draught from a room possessing a fireplace, was suggested by the philanthropic Dr Arnott. It is only necessary to make an aperture into the flue, near the ceiling of the room, and insert therein a tin tube, with a valve at the exterior, capable of opening inwards, but closing when at rest, or when a draught is sent the contrary way. The draught produced by the fire in the flue causes a constant flow of air out of the *upper part* of the room (where most vitiated); and the valve is a more or less effectual protection against back-smoke. This plan can be applied to any existing house at a mere trifle of expense. A more effectual plan, and one which operates when there is no fire in the room, is to establish a tin tube of two or three inches diameter, out of each apartment to be ventilated, causing them all to meet in one general tube, the extremity of which passes into some active flue—for example, that of the kitchen, which is rarely cold—or into any kind of channel in which an active draught can be kept up. Thus there might be a constant passing of fresh air into and through every room of a large house, so that it would be at all times as healthy in this respect as the open fields. At the same time, by means of graduated valves, both draught and supply might be regulated to any degree deemed agreeable. (For various modes of ventilation, see No. 30.)

FOOD.

The second requisite for the preservation of health is—a sufficiency of nutritious food.

Organic bodies, in which are included vegetables as well as animals, are constituted—as explained under PHYSIOLOGY—upon the principle of *a continual waste of substance supplied by continual nutrition.*

The Nutritive System of animals, from apparently the humblest of these to the highest, comprehends an *alimentary tube* or *cavity*, into which food is received, and from which, after undergoing certain changes, it is diffused by means of smaller vessels throughout the whole structure. In the form of this tube, and in the other apparatus connected with the taking of food, there are in different animals varieties of structure, all of which are respectively in conformity with peculiarities in the quality and amount of food which the particular animals are designed to take. The harmony to be observed in these arrangements is remarkably significant of that Creative Design to be traced in all things.

Man designed to live on a Mixed Diet.

Some animals are formed to live upon vegetable substances alone; others are calculated to live upon the flesh of other animals. Herbivorous animals—as the former are called—have generally a long and complicated alimentary tube, because the nutritious part of such food, being comparatively small in proportion to the whole bulk, requires a greater space in which to be extracted and absorbed into the system. The sheep, for example, has a series of intestines twenty-seven times the length of its body. For the opposite reasons, carnivorous or flesh-devouring animals—as the feline tribe of quadrupeds and the rapacious birds—have generally a short intestinal canal. The former class of animals are furnished with teeth, calculated, by their broad and flat surfaces, as well as by the lateral movement of the jaws in which they are set, to mince down the herbage and grain eaten by them. But the carnivorous animals, with wide-opening jaws, have long and sharp fangs to seize and tear their prey. These peculiarities of structure mark sufficiently the designs of nature with respect to the kinds of food required by the two different classes of animals for their support.

The human intestinal canal being of medium length, and the human teeth being a mixture of the two kinds, it necessarily follows that man was designed to eat both vegetable and animal food. As no animal can live agreeably or healthily except in conformity with the laws of its constitution, it follows that man will not thrive unless with a mixture of animal and vegetable food. The followers of Pythagoras argued, from the cruelty of putting animals to death, that it was proper to live on vegetables alone; and eccentric persons of modern times have acted upon this rule. But the ordinances of Nature speak a different language; and

if we have any faith in these, we cannot for a moment doubt that a mixture of animal food is necessary for our wellbeing. On the other hand, we cannot dispense with vegetable food without injurious consequences. In that case, we place in a medium alimentary canal a kind of food which is calculated for a short one, thus violating an arrangement of the most important nature. A balance between the two kinds of food is what we should observe, if we would desire to live a natural and healthy life.

Rules connected with Eating.

In order fully to understand how to eat, what to eat, and how to conduct ourselves after eating, it is necessary that we should be acquainted in some measure with the *process of nutrition*—that curious series of operations by which food is received and assimilated by our system, in order to make good the deficiency produced by waste.

Even in the introductory stage there are certain rules to be observed. Strange as it may appear, to know *how to eat* is physiologically a matter of very considerable importance. Many persons, thinking it all a matter of indifference, or perhaps unduly anxious to despatch their meals, eat very fast. If we are to believe the accounts of travellers, the whole of the mercantile classes in the United States of America eat hurriedly, seldom taking more than ten minutes to breakfast, and a quarter of an hour to dinner. They tumble their meat precipitately into their mouths, and swallow it almost without mastication. This is contrary to an express law of nature, as may be very easily demonstrated.

Food, on being received into the mouth, has two processes to undergo, both very necessary to digestion: it has to be masticated, or chewed down, and also to receive an admixture of saliva. The saliva is a fluid arising from certain glands in and near the mouth, and approaching in character to the gastric juice afterwards to be described. Unless food be well broken down or masticated, and also well mixed up with the salivary fluid, it will be difficult of digestion. The stomach is then called upon to perform, besides its own proper function, that which properly belongs to the teeth and saliva, and it is thus overburdened, often to a very serious extent. The pains of indigestion are the immediate consequence, and more remote injuries are likely to follow.

The importance of the saliva has been shewn in a striking manner on several occasions when food was received into the stomach otherwise than through the mouth. A gentleman, who, in consequence of a stricture in the gullet, had his food introduced by an aperture into that tube, used to suffer severely from indigestion. It is recorded of a criminal, who, having cut his throat in prison without fatal consequences, required to get his food introduced by means of a tube inserted by the mouth, that every time he was fed there was an effusion of saliva to the amount of from six to eight ounces. We cannot suppose that a fluid of a peculiar character would have been prepared in such quantity, when water would serve as well merely to moisten the food, if it had not been designed to act an important part in the business of nutrition.

With regard to mastication, the evidence of its importance is still more decided. A few years ago, a young Canadian, named Alexis St Martin, had a hole made by a shot into his stomach, which healed without becoming closed. It was therefore possible to observe the whole operations of the stomach with the eye. His medical attendant, Dr Beaumont, by these means ascertained that when a piece of solid food was introduced, the gastric juice acted merely on its outside. It was only when the food was comminuted, or made *small*, that this fluid could fully perform its function. When the stomach finds itself totally unable to digest a solid piece of food, it either rejects it by vomiting, or passes it on into the gut, where it produces an irritating effect, and is apt to occasion an attack of colic or flatulency. It must therefore be concluded that *a deliberate mastication of our food is conducive to health, and that fast eating is injurious, and sometimes even dangerous.*

The food, having been properly masticated, is by the action of the tongue thrown into the gullet. It then descends into the stomach, not so much by its own gravity, as by its being urged along by the contractions and motions of the gullet itself. The stomach may be considered as an expansion of the gullet, and the chief part of the alimentary canal. It is, in fact, a membranous pouch or bag, very similar in shape to a bagpipe, having two openings, the one by which the food is admitted, the other that by which it is passed onward. It is into the greater curvature of the bag that the gullet enters; at the lesser, it opens into that adjoining portion of the canal into which the half-digested mass is next propelled.

When food has been introduced, the two orifices close, and that which we may term the second stage in the process of digestion commences. The mass, already saturated with saliva, and so broken down as to expose all its particles to the action of the gastric juice, is now submitted to the action of that fluid, which, during digestion, is freely secreted by the vessels of the stomach. The most remarkable quality of this juice is its solvent power, which is prodigious.

The food exposed to this dissolving agency is converted into a soft, gray, pulpy mass, called *chyme*, which, by the muscular contraction of the stomach, is urged on into the adjoining part of the alimentary canal, called the *duodenum*. This is generally completed in the space of from half an hour to two or three hours; the period varying according to the nature and volume of the food taken, and the degree of mastication and insalivation it has undergone.

In the duodenum, the chyme becomes intimately mixed and incorporated with the bile and pancreatic juices; also with a fluid secreted by the mucous follicles of the intestine itself. The bile is a greenish, bitter, and somewhat viscid fluid, secreted by the liver, which occupies a considerable space on the right side of the body immediately under the ribs. From this organ the bile, after a portion of it has passed up into the adjacent gall-bladder, descends through a small duct, about the size of a goose-quill, into the duodenum. The chyme, when mixed with these fluids, undergoes a change in its appearance: it assumes a yellow colour and bitter taste, owing to the predominance of the bile in the mass; but its character varies according to the nature of the food that has been taken. Fatty matters, tendons, cartilages, white of eggs, &c., are not so readily converted into chyme as fibrous or fleshy, cheesy, and gelatinous substances. The chyme, having undergone the changes adverted to, is urged by the peristaltic motion of the intestines onwards through the alimentary canal. This curious motion of the intestines is caused by the contraction of the muscular coat which enters into their structure, and one of the principal uses ascribed to the bile is that of stimulating them to this motion. If the peristaltic motion be diminished, owing to a deficiency of bile, then the progress of digestion is retarded, and the intestines become constipated. In such cases, calomel, the blue pill, and other medicines, are administered, for the purpose of stimulating the liver to secrete the biliary fluid, that it may quicken, by its stimulating properties, the peristaltic action.

The preceding, however, is not the only use of the bile: it also assists in separating the nutritious from the non-nutritious portion of the alimentary mass, for the chyme now presents a mixture of a fluid termed *chyle*, which is in reality the nutritious portion eliminated from the food. The chyme thus mixed with chyle arrives in the small intestines; on the walls of which a series of exquisitely delicate vessels ramify in every

direction. These vessels absorb or take up the chyle, leaving the rest of the mass to be ejected from the body. The chyle, thus taken up, is carried into little bodies or glands, where it is still further elaborated, acquiring additional nutritious properties; after which corresponding vessels, emerging from these glands, carry along the fluid to a comparatively large vessel, called the thoracic duct, which ascends in the abdomen along the side of the backbone, and pours it into that side of the heart to which the blood that has already circulated through the body returns. Here the chyle is intimately mixed with the blood, which fluid is now propelled into the lungs, where it undergoes, from being exposed to the action of the air we breathe, the changes necessary to render it again fit for circulation. It is in the lungs, therefore, that the process of digestion is completed: the blood has now acquired those nutritive properties from which it secretes the new particles of matter adapted to supply the waste of the different textures of the body. (See Animal Physiology.)

When food is received into the stomach, the secretion of the gastric juice immediately commences; and when a full meal has been taken, this secretion generally lasts for about an hour. It is a law of vital action, that when any living organ is called into play, there is immediately an increased flow of blood and nervous energy towards it. The stomach, while secreting the bile, displays this phenomenon, and the consequence is that the blood and nervous energy are called away from other organs. This is the cause of that chilliness at the extremities which we often feel after eating heartily. So great is the demand which the stomach thus makes upon the rest of the system, that during and for some time after a meal, we are not in a condition to take strong exercise of any kind. Both body and mind are inactive and languid. They are so simply because that which supports muscular and mental activity is concentrated for the time upon the organs of digestion. This is an arrangement of nature which a regard to health requires that we should not interfere with. *We should indulge in the muscular and mental repose which is demanded; and this should last for not much less than an hour after every regular meal.* In that time, the secretion of bile is nearly finished; the new nutriment begins to tell upon the general circulation; and we are again fit for active exertion. The consequence of not observing this rule is often very hurtful. Strong exercise, or mental application, during or immediately after a meal, diverts the flow of nervous energy and of blood to the stomach, and the process of digestion is necessarily retarded or stopped. Confusion and obstruction are thus introduced into the system, and a tendency to the terrible calamity of dyspepsy is perhaps established.

For the same reason that repose is required after a meal, it is necessary in some measure for a little while before. At the moment when we have concluded a severe muscular task—such, for example, as a long walk—the flow of nervous energy and of circulation is strongly directed to the muscular system. It requires some time to allow this flow to stop and subside; and till this takes place, it is not proper to bring the stomach into exercise, as the demand which it makes when filled would not in that case be answered. In like manner also, if we be engaged in close mental application, the nervous energy and circulation being in that case directed to the brain, it is not right all at once to call another and distant organ into play; some time is required to allow of the energy and circulation being prepared to take the new direction. It may therefore be laid down as a maxim, that *a short period of repose, or at least of very light occupation, should be allowed before every meal.*

It is remarkable that these rules, although the natural reasons for them were not perhaps well known, have long been followed with regard to animals upon which man sets a value, while as yet their application to the human constitution is thought of only by a few. Those intrusted with horses and dogs will not allow them to feed immediately after exercise; nor will they allow them to be subjected to exercise for some time after feeding. Experience has also instructed veteran soldiers not to dine the instant that a long march has been concluded, but to wait coolly till ample time has been allowed for all the proper preparations.

Although strong mental and muscular exercise should be avoided before, during, and immediately after a meal, there can be no objection to the light and lively chat which is generally indulged in where several are met to eat together. On the contrary, it is believed that jocund conversation is useful towards the process of nutrition.

Kinds of Food.

It has been shewn, by a reference to the structure of the human intestinal canal, that our food is designed to be a mixture of animal and vegetable substances. There is, it is to be remarked, a power of adaptation in nature, by which individuals may be enabled for a considerable time to live healthily on one or the other kind exclusively or nearly so. The above is nevertheless the general rule, to which it is safest to adhere. It has been found, for instance, that field-labourers, including ploughmen, will live healthily for many years on a diet chiefly farinaceous—that is, composed of the farina of grain. But it is to be feared that the food in this case, though apparently sufficient for health, is only so apparently; and that the constitution, being all the time not supported as it ought to be, breaks down prematurely in a great proportion of instances. It has been said again that the Irish labouring-classes are a remarkably robust race, although their food consists almost exclusively of potatoes. The fact is overlooked, that the Irish eat a quantity of potatoes so enormous, as could not fail to make up in some measure for the want of animal diet. It was found by the Poor-law Commissioners, that the greater number of the peasantry of Ireland, women as well as men, take at their two daily meals in general about nine pounds-weight of this aliment! Such a case is rather to be ranked amongst instances of extraordinary adaptations to a particular variety of food, than as a proof that an unmixed potato-diet is healthy.

Climate has a remarkable effect in modifying the rule as to the mixture and amount of animal and vegetable food. The former has most of a stimulating quality, and this quality is greater in beef, and flesh in general, than in fowl or fish. Now, the inhabitants of torrid countries are, in their ordinary condition, least in need of stimulus; hence they find a simple diet of rice and sago sufficient for them. Those, on the contrary, who dwell in cold countries, need much stimulus; hence they can devour vast quantities of flesh and blubber, with scarcely any mixture of vegetable food.

Inquiries with respect to the comparative digestibility of different kinds of food, are perhaps chiefly of consequence to those in whom health has already been lost. To the sound and healthy, it is comparatively of little consequence what kind of food is taken, provided that some variation is observed, and no excess committed as to quantity. Within the range of fish, flesh, and fowl, there is ample scope for a safe choice. There is scarcely any of the familiar aliments of these kinds but, if plainly dressed, will digest in from two to four hours, and prove perfectly healthy. One rule alone has been pretty well ascertained with respect to animal foods, that they are the more digestible the more minute and tender the fibre may be. They contain more nutriment in a given bulk than vegetable matters, and hence their less need for length of intestine to digest them. Yet it is worthy of notice, that between the chyle produced from animal and that from vegetable food no essential distinction can be observed.

Tendon, suet, and oily matters in general, are considerably less digestible than the ordinary fibre; and

these are aliments which should be taken sparingly. Pickling, from its effect in hardening the fibre, diminishes the digestibility of meat. Dressed shell-fish, cheese, and some other animal foods are avoided by many as not sufficiently digestible.

Farinaceous foods of all kinds—wheat, oaten, and barley bread, oaten porridge, sago, arrow-root, tapioca, and potatoes—are highly suitable to the human constitution. They generally require under two hours for digestion, or about half the time of a full mixed meal. The cottage children of Scotland, reared exclusively upon oaten porridge and bread, with potatoes and milk, may be cited as a remarkable example of a class of human beings possessing in an uncommon degree the blessing of health. Green vegetables and fruit, however softened by dressing, are less digestible, and less healthy as a diet. One important consideration here occurs: there is need for a certain bulk in our ordinary food. Receiving nutriment in a condensed form, and in a small space, will not serve the purpose. This is because the organs of digestion are calculated for receiving our food nearly in the condition in which nature presents it—namely, in a considerable bulk with regard to the proportion of its nutritious properties. The same law applies with respect to the lower animals. When a horse is fed upon corn alone, it does not thrive. Nature did not contemplate that all horses should readily obtain a corn-diet, but looked chiefly to grass and hay for their support. She therefore prepared the organs for the reception of something of considerable volume; and when a food of less volume is persisted in, her law is violated, and fatal consequences ensue. Civilised man is disposed to pay little attention to this rule in his own case. Consulting taste alone, he is apt to refine his food overmuch, and reject what it were better for him to take. The present writer is much inclined to doubt the propriety of grinding off the coarse exterior of wheaten grain. It does not seem by any means likely that nature calculated the human alimentary cavity for the use of the white interior of the grain, exclusive of all the rest, which consists of very different but not less necessary chemical constituents. Wheat forms so large a part of our daily food, that if this be the case, we unquestionably make a departure of a very important kind from the laws of health. Experience is favourable to this view, for the effect of coarse brown bread in relaxing, seems only comparable to that of white bread in constipating the bowels.

Quantity of Food—Number and Times of Meals.

With respect to the amount of food necessary for health, it is difficult to lay down any rule, as different quantities are safe with different individuals, according to their sex, age, activity of life, and some other conditions. There is a general and probably well-founded opinion, that most persons who have the means eat too much, and thereby injure their health. This may be true, and yet it may not be easy to assign to such persons a limit beyond which they ought not to go.

The best authorities are obliged to refer the matter to our own sensations. Dr Beaumont, for example, says that we should not eat till the mind has a sense of *satiety*, for appetite may exceed the power of digestion, and generally does so, particularly in invalids; but to a point previous to that, which 'may be known by the pleasurable sensations of *perfect satisfaction, ease, and quiescence of body and mind.*'

The number and times of meals are other questions as yet undetermined. As the digestion of a meal rarely requires more than four hours, and the waking part of a day is about sixteen, it seems unavoidable that at least three meals be taken, though it may be proper that one, if not two of these, be comparatively of a light nature. Breakfast, dinner, and tea as a light meal, may be considered as a safe, if not a very accurate prescription for the daily food of a healthy person. Certainly four good meals a day is too much. No experiments, as far as we are aware, have been made with regard to the total amount of solids which a healthy person in active life may safely take in a day. It has been found, however, that confined criminals and paupers are healthiest when the daily solids are not much either above or below twenty-four ounces.* Of course, in active life there must be need for a larger allowance, but only to a small extent. We may thus arrive at a tolerably clear conviction of the reality of that excess which is said to be generally indulged in; for certainly most grown people who have the means, not excepting many who pursue very sedentary lives, eat *much more* than twenty-four ounces.

The interval between rising and breakfast ought not to be great, and no severe exercise or task-work of any kind should be undergone during this interval. There is a general prepossession to the contrary, arising probably from the feeling of freedom and lightness which most people feel at that period of the day, and which seems to them as indicating a preparedness for exertion. But this feeling, perhaps, only arises from a sense of relief from that oppression of food under which much of the rest of the day is spent. It is quite inconsistent with all we know of the physiology of aliment, to suppose that the body is capable of much exertion when the stomach has been for several hours quite empty. We have known many persons take long walks before breakfast, under an impression that they were doing something extremely favourable to health. Others we have known go through three hours of mental task-work at the same period, believing that they were gaining so much time. But the only observable result was, to subtract from the powers of exertion in the middle and latter part of the day. In so far as the practice was contrary to nature, it would likewise of course produce permanent injury. Only a short saunter in the open air, or a very brief application to business or task-work, can be safely indulged in before breakfast.

Variety of Food.

A judicious variation of food is not only useful, but important. There are, it is true, some aliments, such as bread, which cannot be varied, and which no one ever wishes to be so. But apart from one or two articles, a certain variation or rotation is much to be desired, and will prove favourable to health. There is a common prepossession respecting *one dish*, which is more spoken of than acted upon. In reality, there is no virtue in this practice, excepting that, if rigidly adhered to, it makes excess nearly impossible, no one being able to eat to satiety of one kind of food. There would be a benefit from both a daily variation of food and eating of more than one dish at a meal, *if moderation were in both cases to be strictly observed;* for the relish to be thus obtained is useful, as promotive of the flow of nervous energy to the stomach, exactly in the same manner as cheerfulness is useful. The policy which would make food in any way unpleasant to the taste is a most mistaken one; for to eat with languor, or against inclination, or with any degree of disgust, is to lose much of the benefit of eating. On the other hand, to cook dishes highly, and provoke appetite by artificial means, are equally reprehensible. Propriety lies in the mean between the two extremes.

Beverages.

The body containing a vast amount of fluids, which are undergoing a perpetual waste, there is a necessity for an occasional supply of liquor of some kind, as well as of solid aliment. It remains to be considered what is required in the character or nature of this liquor,

* See two papers on food, in Nos. 366 and 368 of *Chambers's Edinburgh Journal*, old series.

to make it serve as a beverage consistently with the preservation of health.

It is scarcely necessary to remark how men in all ages, and almost all climes, have indulged in liquors containing a large infusion of alcohol, or how widespread in our own society is the custom of drinking considerable quantities of wine, spirits, and beer, both at meals and on other occasions. Against habits so inveterate, it is apt to appear like fanaticism to make any decided objection; yet the investigator of the laws which regulate health is bound to consider, above all things, how any particular habit bears upon the human constitution, and to state what is the result of his inquiries, however irreconcilable it may be with popular prejudice or practice.

'The primary effect of all distilled and fermented liquors,' says Dr Combe, 'is to *stimulate the nervous system and quicken the circulation*.' They may thus be said to have a larger measure of the effect which animal food has upon the system. It is therefore the less surprising that those tropical nations which live most on farinaceous diet are also found to be those which have the least propensity to the drinking of ardent spirits; while those northern nations which live most on animal food have the exactly contrary inclination with respect to liquor, the Scandinavian tribes being notoriously the greatest sots that have ever been known. Dr Combe admits that in some conditions of the system, when the natural stimulus is defective, it may be proper to take an artificial supply in the form of ardent and fermented liquors. 'There are,' he says, 'many constitutions so inherently defective in energy, as to derive benefit from a moderate daily allowance of wine; and there are many situations in which even the healthiest derive additional security from its occasional use. If, for example, a healthy person is exposed to unusual and continued exertion in the open air, or to the influence of anxious and depressing watchfulness, a moderate quantity of wine with his food may become the means of warding off actual disease, and enabling him to bear up uninjured, where without it he would have given way.' But Dr Combe at the same time declares, in the most decided language, that when the digestion is good, and the system in full vigour, the bodily energy is easily sustained by nutritious food, and 'artificial stimulant *only increases the wasting of the natural strength*.' Nearly all physicians, indeed, concur in representing ardent liquors as unfavourable to the health of the healthy, and as being, in their excess, highly injurious. Even the specious defence which has been set up for their use, on the ground that they would not have been given to man if they had not been designed for general use, has been shewn to be ill-founded, seeing that *vinous fermentation*, from which they are derived, is not a healthy condition of vegetable matter, but a stage in its progress to decay. Upon the whole, there can be little doubt that these liquors are deleterious in our ordinary healthy condition; and that pure water, toast-water, milk, whey, and other simple and unexciting beverages, would be preferable—the first being the most natural—if we could only consent to deny ourselves further indulgence.

CLEANLINESS.

To keep the body in a cleanly condition is the third important requisite for the preservation of health. This becomes necessary, in consequence of a very important natural process which is constantly going on near and upon the surface of the body.

The process in question is that of *perspiration*. The matter here concerned is a watery secretion, produced by glands near the surface of the body, and sent up through the skin by channels imperceptibly minute and wonderfully numerous. From two to six pounds of this secretion is believed to exude through these channels or *pores* in the course of twenty-four hours, being, in fact, the chief form taken by what is called the waste of the system, the remainder passing off by the bowels, kidneys, and lungs. To promote the free egress of this fluid is of the utmost importance to health; for when it is suppressed, disease is ready to fall upon some of the other organs concerned in the discharge of waste.

One of the most notable checks which perspiration experiences is that produced by a current of cold air upon the skin, in which case the pores instantly contract and close, and the individual is seized with some ailment either in one of the other organs of waste, whichever is in him the weakest, or in the internal lining of some part of the body, all of which is sympathetic with the condition of the skin. A result of the nature of that last described is usually recognised as a cold or catarrh. We are not at present called on particularly to notice such effects of checked perspiration, but shall allude to others of a less perceptible, though not less dangerous nature.

The fluid alluded to is composed, besides water, of certain salts and animal matters, which, being solid, do not pass away in vapour, as does the watery part of the compound, but rest on the surface where they have been discharged. There, if not removed by some artificial means, they form a layer of hard stuff, and unavoidably impede the egress of the current perspiration. By cleanliness is merely meant the taking proper means to prevent this or any other extraneous matter from accumulating on the surface, to the production of certain hurtful consequences.

Ablution or washing is the best means of attaining this end; and accordingly it is well for us to wash or bathe the body frequently. Many leave by far the greater part of their bodies unwashed, except perhaps on rare occasions, thinking it enough if the parts exposed to common view be in decent trim. If the object of cleaning were solely to preserve fair appearances, this might be sufficient; but the great end, it must be clearly seen, is to keep the skin in a fit state for its peculiar and very important functions. Frequent change of the clothing next to the skin is of course a great aid to cleanliness, and may partly be esteemed as a substitute for bathing, seeing that the clothes absorb much of the impurities, and, when changed, may be said to carry these off. But still this will not serve the end nearly so well as frequent ablution of the whole person. Any one will be convinced of this who goes into a bath, and uses the flesh-brush in cleansing his body. The quantity of scurf and impurity which he will then remove, from a body which has changes of linen even once a day, will surprise him.

Considering the importance of personal cleanliness for health, it becomes a great duty of municipal rulers to afford every encouragement in their power to the establishment of public baths for the middle and working classes, and to extend and protect all existing facilities for washing clothes, as well as for private supplies of water. Baths should neither be very cold nor very warm, but in an agreeable medium; and they should never be taken within three hours of a meal. Nature may be said to make a strong pleading for their more general use, in the remarkably pleasing feeling which is experienced in the skin after ablution.

EXERCISE.

The constitution of external nature shews that man was destined for an active existence, as without labour scarcely any of the gifts of Providence are to be made available. In perfect harmony with this character of the material world, he has been furnished with a muscular and mental system, constructed on the principle of being fitted for exertion, and requiring exertion for a continued healthy existence. Formed as he is, it is not possible for him to abstain from exertion without very hurtful consequences.

Muscular Exercise.

With regard to merely bodily exercise, it is to be observed, in the first place, that we have no fewer than four hundred muscles, each designed to serve some particular end in locomotion, or in operating upon external objects. A sound state of body depends very much upon each of these muscles being brought into action in proper circumstances, and to a suitable extent. There is even a law, operating within a certain range, by which each muscle will gain *in strength and soundness* by being brought into a proper degree of activity.

The process of waste and renovation may be said to be always going on in the body, but it does not go on with permanent steadiness, unless the muscular system be exercised. Whenever one of the organs is put into exertion, this process becomes active, and the two operations of which it consists maintain a due proportion to each other. A greater flow of blood and of nervous energy is sent to the organ, and this continues as long as it is kept in activity. When one state of action follows close upon another, the renovating part of the process rather exceeds the waste, and an accretion of new substance, as well as an addition of fresh power, takes place. On the contrary, when an organ is little exercised, the process of renovation goes on languidly, and to a less extent than that of waste, and the parts consequently become flabby, shrunken, and weak. Even the bones are subject to the same laws. If these be duly exercised in their business of administering to motion, the vessels which pervade them are fed more actively with blood, and they increase in dimensions, solidity, and strength. If they be little exercised, the stimulus required for the supply of blood to them becomes insufficient; imperfect nutrition takes place; and the consequences are debility, softness, and unfitness for their office. Bones may be so much softened by inaction, as to become susceptible of being cut by a knife. In a less degree, the same cause will produce languor and bad health.

It is of the utmost importance to observe that the exercise of any particular limb does little besides improving the strength of that limb; and that, in order to increase our general strength, the whole frame must be brought into exercise. The blacksmith, by wielding his hammer, increases the muscular volume and strength of his right arm only, or if the rest of his body derives any advantage from his exercise, it is through the general movement which the wielding of a hammer occasions. One whose profession consists in dancing or leaping, for the same reason, chiefly improves the muscles of his legs. The right hands of most persons, by being more frequently employed than the left, become sensibly larger as well as stronger. A still more striking illustration of the principle is to be found in a personal peculiarity which has been remarked in the inhabitants of Paris. Owing to the uneven nature of the pavement of that city, the people are obliged to walk in a tripping manner on the front of their feet; a movement which calls the muscles of the calves of the legs into strong exertion. It is accordingly remarked that a larger proportion of the people of Paris are distinguished by an uncommon bulk in this part of their persons than in other cities.

In order, then, to maintain in a sound state the energies which nature has given us, and, still more particularly, to increase their amount, *we must exercise them*. If we desire to have a strong limb, we must exercise that limb; if we desire that the whole of our frame should be sound and strong, we must exercise the whole of our frame. It is mainly by these means that health and strength are to be preserved and improved. There are rules, however, for the application of these laws of our being.

1. That bodily exercise may be truly advantageous, the parts must be in a state of sufficient health to endure the exertion. A system weakened by disease or long inaction must be exercised very sparingly, and brought on to greater efforts very gradually, otherwise the usual effects of over-exercise will follow. In no case must exercise be carried beyond what the parts are capable of bearing with ease; otherwise, a loss of energy, instead of a gain, will be the consequence.

2. Exercise, to be efficacious even in a healthy subject, must be excited, sustained, and directed by that nervous stimulus which gives the muscles the principal part of their strength, and contributes so much to the nutrition of parts in a state of activity. To explain this, it must be mentioned that to produce motion requires the co-operation of the muscular fibre with two sets of nerves, one of which conveys the command of the brain to the muscle, and causes its contraction, while the other conveys back to the brain the peculiar sense of the state of the muscle, by which we judge of the fitness of the degree of contraction which has been produced to accomplish the end desired, and which is obviously an indispensable piece of information to the mind in regulating the movements of the body. The nervous stimulus thus created, will enable a muscle in the living frame to bear the weight of a hundred pounds, while, if detached, it would be torn asunder by one of ten. It is what causes men in danger, or in the pursuit of some eagerly desired object, to perform such extraordinary feats of strength and activity. In order, then, to obtain the advantage of this powerful agent, *we must be interested in what we are doing*. A sport that calls up the mental energy, a walk towards a place which we are anxious to reach, or even an exercise which we engage in through a desire of invigorating our health and strength, will prove beneficial, when more of actual motion, performed languidly, may be nearly ineffectual.

3. The waste occasioned by exercise must be duly replaced by food; as, if there be any deficiency in that important requisite, the blood will soon cease to give that invigoration to the parts upon which increased health and strength depend.

Kinds of Bodily Exercise.

Exercise is usually considered as of two kinds—active and passive. The active consists in walking, running, leaping, riding, fencing, rowing, skating, swimming, dancing, and various exercises, such as those with the poles, ropes, &c., prescribed in gymnastic institutions. The passive consists in carriage-riding, sailing, friction, swinging, &c. (For various modes of agreeable recreation, see articles on INDOOR and OUTDOOR AMUSEMENTS—Volume II.)

Walking is perhaps the readiest mode of taking exercise, and the one most extensively resorted to. If it brought the upper part of the body as thoroughly into exertion as the lower, it would be perfect, for it is gentle and safe with nearly all except the much debilitated. To render it the more effectual in the upper part of the body, it were well to walk at all times, when convenient, *singly*, and allow the arms and trunk free play. It is best to walk with a companion, or for some definite object, as the flow of nervous energy will be by these means promoted, and the exercise be rendered, as has been already explained, the more serviceable.

Very long or rapid walks should not be attempted by individuals of sedentary habits, nor by weakly persons. Their frames are totally unprepared for such violent exertion. When a person who has been long confined at still employments, finds himself at liberty to indulge his inclination for a ramble of a few days in the country, he should begin with slow and short marches, and be content therewith till his body is hardened for greater efforts. This is a rule followed in the army with respect to regiments which are about to undertake long marches. Every summer, many youths, from

ignorance, do themselves great injury, by undertaking pedestrian excursions much beyond their strength. Jaded to the last degree, and incapable of enjoying anything presented to their observation, they nevertheless persist in making out some appointed number of miles per day, never once thinking of the outrage they are committing upon themselves, and only looking to the glory of executing their task, the only pleasure they find in the journey. Serious consequences—consumption not unfrequently—follow such ill-advised efforts.

With respect to very violent walking, Dr Johnson records some effects from it, of a remarkable nature, as occurring in his own case. 'In my own person,' says he, 'I had some years ago a very severe and alarming instance of the bad effects of too great muscular action, occasioned by a habit of walking very fast. After a day and night of unusual fatigue and rapid pedestrian exertion, together with considerable mental anxiety, I was suddenly seized with an intermission of the pulse at irregular periods. During each intermission, I felt the heart give a kind of struggle, as it were, and strike with great violence against the ribs, accompanied by a peculiar and most distressing sensation in the cardiac region, which I cannot describe.' These symptoms became aggravated, and lasted for eight weeks, 'during which time,' he continues, 'I used gentle horse-exercise, and kept, when at home, in a horizontal position. At length the heart gradually lost its morbid irritability, and at the end of fourteen or fifteen weeks I could walk as well as ever.'

Running is an exercise which is intermediate between walking and leaping; it consists, in fact, of a series of leaps performed in progression from one foot to another, and the degree of its rapidity bears a constant proportion to the length of the individual and successive leaps. During this exercise, the individual is obliged to take long inspirations, and make slow expirations; the air-cells of the lungs are thereby distended, and the action of the heart being at the same time increased, and the circulation through the lungs much accelerated, a sense of oppression is felt on the chest, which is often exceedingly painful: when the violent action is discontinued, the heart palpitates with intermitting strokes, in the endeavour to recover its natural equilibrium of motion. Although this and other gymnastic exercises—such as leaping, wrestling, throwing heavy weights, &c.—may, when judiciously had recourse to, invigorate the body, yet from apprehension of the evils and accidents which may be so occasioned, young persons ought not to be permitted to engage extensively in such exercises, except under the care of some one well acquainted with gymnastics.

Fencing is, of all active exercises, that which is the most commendable, inasmuch as it throws open the chest, and at the same time calls into action the muscles both of the upper and lower extremities. Add to this that it improves very much the carriage of the body; for which reason it may be reckoned a branch of polite education. The salutary effects of the other exercises which are taught in gymnastic institutions—such as exercise with the ropes, poles, pulleys, &c.—in increasing the strength of the body, will be seen by consulting Mr Roland's Treatise on Gymnastics, where will be found a table shewing the amount of the increasing growth and strength of the body in a given time during the employment of these exercises.

Dancing is exhilarating and healthful, and seems to be almost the only active exercise which the despotic laws of conventionality permit young ladies to enjoy. We can scarcely consider modern quadrilles, elegant though they be, as exercise, seeing that they differ little from the most common walking movements. But country-dances, reels, and hornpipes, are genuine exercise, and their less refinement may be considered as amply compensated by the superior benefit which they are calculated to confer upon health.

Riding is generally classed among the passive exercises, but in reality it is one which involves much action of the whole frame, and as such is very useful. Pursued solitarily, it has the drawback of being somewhat dull; but when two or three ride in company, a sufficient flow of the nervous energy may be obtained.

The amount of bodily exercise which should be taken must vary according to the habits, strength, and general health of the individual. It was an aphorism of Boerhaave, that every person should take at least two hours' exercise in the day; and this may be regarded as a good general rule.

Mental Exercise.

Having thus explained the laws and regulations by which exercise may be serviceable to the physical system, we shall proceed to shew that the same rules hold good respecting the mental faculties. These, as is generally allowed, however immaterial in one sense, are connected organically with the brain—a portion of the animal system nourished by the same blood, and regulated by the same vital laws, as the muscles, bones, and nerves. As, by disuse, muscle becomes emaciated, bone softens, blood-vessels are obliterated, and nerves lose their natural structure; so by disuse does the brain fall out of its proper state and create misery to its possessor; and as, by over-exertion, the waste of the animal system exceeds the supply, and debility and unsoundness are produced, so by over-exertion are the functions of the brain liable to be deranged and destroyed. The processes are physiologically the same, and the effects bear an exact relation to each other. As with the bodily powers, the mental are to be increased in magnitude and energy by a degree of exercise measured with a just regard to their ordinary health and native or habitual energies. Corresponding, moreover, to the influence which the mind has in giving the nervous stimulus so useful in bodily exercise, is the dependence of the mind upon the body for supplies of healthy nutriment. And, in like manner with the bodily functions, each mental faculty is only to be strengthened by the exercise of itself in particular. Every part of our intellectual and moral nature stands, in this respect, exactly in the same situation with the blacksmith's right arm and the lower limbs of the inhabitants of Paris—each must be exercised for its own sake.

The fatal effects of the disuse of the mental faculties are strikingly observable in persons who have the misfortune to be solitarily confined, many of whom become insane, or at least weak in their intellects. It is also observable in the deaf and blind, among whom, from the non-employment of a number of the faculties, weakness of mind and idiocy are more prevalent than among other people. This is indeed a frequent predisposing cause of every form of nervous disease.

The loss of power and health of mind from imperfect or partial exercise of the faculties, is frequently observable in the country clergy, in retired merchants, in annuitants, in the clerks of public offices, and in tradesmen whose professions comprehend a very limited range of objects. There is no class, however, in whom the evil is more widely observable than in those females who, either from ignorance of the laws of exercise, or from inveterate habit, spend their lives in unbroken seclusion, and in the performance of a limited range of duties. All motive is there wanting. No immediate object of solicitude ever presents itself. Fixing their thoughts entirely on themselves, and constantly brooding over a few narrow and trivial ideas, they at length approach a state little removed from insanity, or are only saved from that, perhaps, by the false and deluding relief afforded by stimulating liquors. In general, the education of such persons has given them only a few *accomplishments*, calculated to afford employment to one or two of the minor powers of the mind, while

all that could have engaged the reflecting powers has been omitted. Education, if properly conducted, would go far to prevent these evils.

On the other hand, excessive exercise of the brain, by propelling too much blood to it, and unduly distending the vessels, is equally injurious with its disuse. And not only are fatal effects to be apprehended from undue mental task-work, but also from that constant *stretch* of the mind which attends an unduly anxious and watchful disposition. The ancients had some notion of the impropriety of an incessant exertion of the mind, and rebuked it by their well-known proverb —*Apollo does not keep his bow always bent.* But they had comparatively little experience of the oppressive mental labours endured by large portions of modern society. Irrational, and in some respects dangerous, as many of the habits of our ancestors were, it is questionable if they suffered so much from these causes as their successors do from virtuous but overtasking exertion. To maintain what each man conceives to be a creditable place in society, now requires such close and vigorous exertions, that more, we verily believe, perish in the performance of duties in themselves laudable, than formerly sank under fox-hunting, toast-drinking, and the gout.

It is in large cities that this unintentional kind of self-destruction is most conspicuously exemplified. And it is in London, above all other places, that the frenzy is to be observed in its most glaring forms. To spend nine hours at a time in business, without food or relaxation, is not only not uncommon, but an almost universal practice, among the citizens of London: from a breakfast at eight to a chop at five, they are never, to use an expressive phrase, *off the stretch.* Upon a stomach enfeebled by exhaustion, they then lay the load of a full meal, which perfect leisure would hardly enable them to digest. But far from waiting to digest it, they have no sooner laid down knife and fork, than away they must once more rush to business—not perhaps willingly, for nature tells them that it would be agreeable to rest; but then—but then business *must* be attended to. If nature were to punish the daily transgression by the nightly suffering, we should find few who, for the sake of pecuniary gain, would thus expose themselves to misery. But she runs long accounts with her children, and, like a cheating attorney, seldom renders her bill till the whole subject of litigation has been eaten up. Paralysis at fifty comes like the mesne process upon the victim of commercial enthusiasm,* and either hurries him off to that prison from which there is no liberation, or leaves him for a few years organically alive to *enjoy* the fruits of his labours.

The absurdity of an ignorance or weakness of this kind is perhaps still more striking when it occurs in individuals who make the acquisition of knowledge the chief aim of life. As the world is at present situated, it is possible to acquire learning upon almost every subject, and an infinite amount of knowledge, useful and otherwise, without even by chance lighting upon a knowledge of the most indispensable observances necessary for the preservation of a sound mind in a sound body. Half of the multiform languages of Asia may be mastered, while the prodigy who boasts so much learning knows not that to sit a whole day within doors at close study is detrimental to health; or, if he knows so much, deliberately prefers the course which leads to ruin.

The premature extinction of early prodigies of genius is generally traceable to the same cause. We read that, while all other children played, they remained at home to study; and then we learn that they perished in the bud, and balked the hopes of all their admiring friends. The ignorant wonder is of course always the greater when life is broken short in the midst of honourable undertakings. We wonder at the inscrutable decrees which permit the idle and dissolute to live, and remove the ardent benefactor of his kind, the hope of parents, the virtuous, and the self-devoted; never reflecting that the highest moral and intellectual qualities avail nothing in repairing or warding off a decided injury to the physical system, which is regulated by laws of a different, but of as imperative a nature. The conduct of the Portuguese sailors in a storm, when, instead of working the vessel properly, they employ themselves in paying vows to their saints, is just as rational as most of the notions which prevail on this subject in the most enlightened circles of British society.

It ought to be universally known, that the uses of our intellectual nature are not to be properly realised without a just regard to the laws of that perishable frame with which it is connected; that, in cultivating the mind, we must neither overtask nor undertask the body, neither push it to too great a speed, nor leave it neglected; and that, notwithstanding this intimate connection and mutual dependence, the highest merits on the part of the mind will not compensate for muscles mistreated, or soothe a nervous system which severe study has tortured into insanity. To come to detail—it ought to be impressed on all, that to spend more than a moderate number of hours in mental exercise, diminishes insensibly the powers of future application, and tends to abbreviate life; that no mental exercise should be attempted immediately after meals, as the processes of thought and of digestion cannot be safely prosecuted together; and that without a due share of exercise to the whole of the mental faculties, there can be no soundness in any, while the whole corporeal system will give way beneath a severe pressure upon any one in particular. These are truths completely established with physiologists, and upon which it is undeniable that a great portion of human happiness depends.

Repose a Condition demanded by Exercise.

Exercise demands occasional periods of repose, and, in particular, that a certain part of every twenty-four hours be spent in sleep. After having been engaged in daily occupations for fourteen or sixteen hours, a general feeling of fatigue and weakness is induced; the motions of the body become difficult, the senses confused, the power of volition or *will* suspended, and the rest of the mental faculties, becoming more and more inactive, sink at length into a state of unconsciousness. The sense of sight first ceases to act by the closing of the eyelids; then the senses of taste and smell become dormant; and then those of hearing and touch. The muscles also dispose themselves with a certain reference to ease of position, those of the limbs having grown indolent before those that support the head, and those that support the head before those of the trunk. In proportion as these phenomena proceed, the respiration becomes slower and more deep, the circulation diminishes in impetus, the blood proceeds in great quantity towards the head, and all the functions of the internal organs become retarded. In this state, shut out, as it were, from the external world, the mind still retains part of its wonted activity, deprived, however, of the guidance of judgment and the power of *distinct* recollection; in consequence of which it does not perceive the monstrous incongruities of the imagery which sweeps before it, and takes but imperfect cognizance of the time which elapses.

It may be laid down as an axiom, that the more uninterrupted sleep is, the more refreshing and salutary will be its effects; for, during this period, the body undoubtedly acquires an accession of nervous energy, which restlessness, however induced, must disturb; and therefore the state of the body before going to sleep,

* Of the frequent occurrence of premature paralysis, in consequence of the mode of life above described, we are assured by a metropolitan physician of the greatest eminence.

the kind of bed, and the manner of clothing, require especial attention. As the functions of the body are performed more slowly during our sleeping than our waking hours, a full meal or supper, taken immediately before going to bed, imposes a load on the stomach which it is not in a condition to digest, and the unpleasant consequence of oppressive and harassing dreams is almost certain to ensue. When the sleeper lies upon his back, the heart pressing, while pulsating, on the lungs, gives rise to a sense of intolerable oppression on the chest, which seems to bear down upon the whole body, so that in this painful state not a muscle will obey the impulse of the will, and every effort to move appears to be altogether unavailing. This constitutes *incubus* or *nightmare;* and it may be observed that, as acidity on the stomach, or indigestion, gives rise to such dreams, so all dreams of this disturbed character are converse indications of indigestion; for which reason, the great physiologist Haller considered dreaming to be a symptom of disease. It is certain that the dreams of healthy persons are the lightest and most evanescent.

The kind of bed on which we repose requires attention. Some are advocates for soft, others for hard beds; hence some accustom themselves to feather-beds, others to mattresses. The only difference between a soft and a hard bed is this—that the weight of the body in a soft bed presses on a larger surface than on a hard bed, and thereby a greater degree of comfort is enjoyed. Parents err in fancying that a very hard bed contributes to harden the constitution of their children; for which reason they lay them down on mattresses, or beds with boarded bottoms. A bed for young children cannot be too soft, provided the child does not sink into it in such a manner that the surrounding parts of the bed bend over and cover the body. The too great hardness of beds, says Dr Darwin, frequently proves injurious to the shape of infants, by causing them to rest on too few parts at a time; it also causes their sleep to be uneasy and unrefreshing. The universal analogy derived from other animals evinces the truth of this doctrine, both in respect to the softness and due degree of warmth of their beds. Birds line the nests of their young with feathers; the eider duck and the rabbit pluck the down from their own breast to increase the softness of the beds of their tender offspring, and brood over them with their wings, or clasp them to their bosoms for the sake of warmth. For this reason, it is better that delicate children should sleep with a bedfellow than alone; for in this case, if any part of the body becomes cold, the child instinctively places that part in contact with the warmer body of its companion. So, also, it is better for a new-born infant to sleep with its mother in winter, or with its nurse, than in a solitary crib by the bedside.

When in bed, the head should be always higher than the feet; and those subject to palpitation of the heart should lie with their heads considerably higher. Night-clothes should never consist of more than a chemise or shirt of cotton or linen, with a flannel shirt beneath. It is also highly improper to sleep in a bed overloaded with clothes; the body is thereby heated, and feverishness and restlessness induced. Accordingly, persons who complain of sleeplessness should look to the quantity of their bed-clothing; for the unnecessary addition of a single blanket may be the sole cause of the annoyance. It is also imprudent to lie with the head entirely within the bed-clothes; for in this case the same air which has been already breathed must be again and again inhaled. For the same reason, the curtains should not be drawn closely round the bed. Washing the face and hands, and brushing the teeth, before going to bed, will be found to contribute materially to comfort. Whatever be the time chosen for sleep, it is evident that no person can with impunity convert day into night. Eight o'clock for children, and eleven for adults, may be recommended as good hours for retiring to rest. It is well known that children require more sleep than adults; and more sleep is requisite in winter than in summer. The average duration of sleep which may be recommended for adults is *eight* hours; but much depends upon habit, and many persons require only six. On getting up, ablution for the sake of cleanliness and the promotion of the right action of the skin, becomes important. The washing of the entire person is desirable for these reasons; and where this cannot be effected, the cleansing of at least the face, neck, hands, and teeth, ought on no account to be neglected. The most simple powder for the teeth is finely pounded charcoal, a little of which will clear away all impurities, destroy any fetor, and preserve the teeth. On leaving the bedroom, the windows should be opened, and the clothes of the bed turned down, in order that the exhalations of the body during sleep may be dissipated. If, instead of this, the bed be made immediately after we have risen, these exhalations are again folded up with the clothes—a practice which is not consonant either with cleanliness or with health.

TEMPERATURE.

The fifth important requisite for health is, that the body be kept in a temperature suitable to it.

The degree of heat indicated by 64 degrees of Fahrenheit's thermometer, or that of a temperate summer day, is what the human body finds it agreeable to be exposed to when in a state of inactivity. In air much colder, the body experiences an unpleasant sensation, unless some warm clothing be worn, or a pretty active exercise indulged in. When, either by natural or artificial means, the body is kept in a suitable state of warmth, the functions of the circulation and perspiration in the skin go on healthily; it is red, in consequence of the blood being urged into the capillaries or minute vessels near the surface; it is also soft and moist, from the action of the glands for secreting the waste fluid and its free egress through the pores. This is a condition of great comfort; and the appearance of those who enjoy it, conveys to others the notion that they are in good health. When, on the contrary, there is a much lower temperature, the functions of the vessels connected with the skin are liable to be considerably deranged. The vessels, in these circumstances, contract; the blood is driven inwards, where it sometimes occasions diseases of a dangerous nature; the perspiration also being prevented from passing out by its usual channels, catarrhal complaints ensue, sometimes ending in consumption.

It is of the more importance to make these facts generally known, as a notion prevails that exposure to a painful degree of cold tends to induce hardiness of constitution and to promote health. Undoubtedly there may be harm from an opposite extreme, and we know well that excessive clothing and living in overheated apartments are detrimental to health. But safety lies in a medium between the two extremes. There is a degree of warmth which is both agreeable and healthy, and which it is desirable to have around us as constantly as possible—generally from 60 to 64 degrees Fahrenheit.

There is no period of life at which warmth is of more consequence than in infancy. In a very young babe, the circulation is almost altogether confined to the surface, the internal organs being as yet in a very weak state. In such circumstances, to plunge the child into cold water, from an idea of making it hardy, as is customary in some countries, and among ignorant persons in our own, is the height of cruelty and folly; for the unavoidable consequence is, that the blood is thrown in upon the internal organs, and inflammation, bowel-complaints, croup, or convulsions, are very likely to ensue. A baby requires to be kept at a temperature above what is suitable to a grown person; it should be warmly, but not heavily clothed; the room where it is kept should be maintained at a good, but not oppressive

heat; and it should never be put into other than tepid water. It should not be exposed to the open air for some days after its birth.

At all periods of life, it is most desirable to avoid exposure to very low temperatures, especially for any considerable length of time. To sit long in cold school-rooms or work-rooms, with the whole body, and especially the feet, in a chilled condition, is very unfavourable to the health of young people. It is not possible that a condition so adverse to the healthy action of the cutaneous vessels should not lead, if long persisted in, to very bad consequences. Those who are compelled to be sedentary, should make it their endeavour to obtain a sufficiently high temperature, either by warming their apartments sufficiently, or thickening their clothing. Common fires, though delightful from their cheerful look, are confessedly very inadequate, in most circumstances, to heat large work-rooms, school-rooms, or even the larger class of sitting-rooms; not to speak of the great objection which has been made to them on the score of economy, three-fourths of their heat being sent off through the chimney. It is most desirable that some means in which the public could have confidence were devised for thoroughly, and at the same time healthily, warming large apartments. Stoves enclosed in large iron-plate cases (Arnott's stoves), pipes of hot water or of steam, and blasts of heated air, are amongst the most conspicuous plans tried within the last few years. (See WARMING, No. 30.)

Clothing should be in proportion to the temperature of the climate and the season of the year; and where there are such abrupt transitions from heat to cold as in our own country, it is not safe ever to go very thinly clad, as we may in that case be exposed to a sudden chill before we can effect the proper change of dress. Very fatal effects often result to ladies from incautiously stepping out of heated rooms in the imperfect clothing which they ludicrously style *full-dress:* all such injuries might be avoided by putting on a sufficiency of shawls or cloaks, and allowing themselves a little time in the lobby to cool. The under-clothing in this country should be invariably of flannel, which is remarkably well calculated to preserve uniformity of temperature, as well as to produce a healthy irritation in the skin. While the value of comfortable clothing is fully acknowledged, we should never lose sight of the value of exercise for keeping up a kindly glow upon the surface, and for the support of a high tone of general health. Any one who, neglecting this, should live constantly in a warm apartment, or only go out of doors muffled up in a mass of clothing, would speedily suffer from a relaxed state of the system, and become so susceptible of damage from the slightest change of temperature in the atmosphere, that the most dangerous consequences might be apprehended.

Wet clothes applied to any part of the body, when it is in an inactive state, have an instantaneous effect in reducing the temperature, this being an unavoidable effect of the process of evaporation which then takes place. Hence it is extremely dangerous to sit upon damp ground, or to remain at rest for a single minute with wetted feet, or any other part of the body invested in damp garments. Dampness in the house in which we live has the same effect, and is equally dangerous. The chill produced by the evaporation from the wetted surface checks the perspiration, and sends the blood inwards to the vital parts, where it tends to produce inflammatory disease. Few persons seem to be aware of these truths. We find young men heedlessly getting their feet wet, and sitting with them in that condition, thereby incurring the most deadly peril. Young women commit a similar folly when they walk out in thin shoes in a wet or cold day. Exposure to wet, damp, or cold, is of comparatively little moment when the body, by a course of exercise or training, has been prepared to endure these conditions. Thus a person brought up delicately, or much within doors, would be killed by that which would have little or no effect on a ploughman. It is therefore worthy of being suggested as a line of policy, that no one should accustom him or her self to a pampered or too delicate mode of life. Every one should, if possible, go out daily, both in good and bad weather, with clothing corresponding to the nature of the weather, and in this way strengthen and harden the constitution to endure all ordinary and reasonable exposure. It is important, however, to note, that even the hardiest persons are never safe from the effects of wet clothes and other modes of exposure to a reduced temperature. No complaint is more common among out-of-door labourers, and also poor people in damp lodgings, than rheumatism. This is an affection produced solely by a violation of the natural law which demands that the body should not be chilled. Rheumatism is produced alike from exposure to a shower or to a draught of cold air when the body is warm, and from sitting with the feet on a cold stone or clay floor; the only difference, perhaps, being, that the rheumatism is in one case in the shoulders, and in the other in the legs. Let us therefore impress on all the propriety of avoiding chills, the effects of which may be much more fatal than a simple attack of rheumatism. When rheumatism has been contracted, the best remedy for its expulsion, if adopted in time, is friction of the part; if well rubbed before a fire with flour of mustard, so as to cause a counter-irritation on the surface, the internal complaint may be expelled.

Errors in Dress.

This is perhaps the most appropriate place in which to introduce some remarks upon errors in dress. The integuments which nature calls upon us to put on for the sake of warmth, are too often made the means of inflicting serious injury, either through ignorance, fashion, or caprice. It is therefore necessary, in a treatise on the preservation of health, to advert in emphatic terms to this subject.

It is scarcely too much to say that there is no part of the human frame, from the sole of the foot to the crown of the head, which has not been, and is not at this moment, mistreated by fashion. We laugh at the Chinese ladies, who have their feet constrained by iron moulds into mere bulbous appendages to the limbs; but we never reflect that, amongst ourselves, errors only inferior in degree are constantly committed. The foot naturally spreads out, fan-like, from the heel to the toes. But instead of having our shoes formed in the same triangular shape, they are made in a lozenge form, truncated at the front, the toes being thus perverted from their radiating arrangement into one exactly the opposite; so that they become crushed under one another, and deprived of a great part of that muscular power by which they were designed to propel our bodies in walking. In the greater height usually given to the heels of shoes, another important deviation from nature is committed. When the heel is raised above the level of the ball of the foot, a complete derangement takes place in the muscles of locomotion; the power of the limb is impaired; and the whole body is thrown off its equipoise. It is impossible, in such circumstances, to exercise the body as it ought to be. The foot is also forced or plugged down into the narrow front of the shoe, where the toes become liable to the grievance of corns. Thus the free healthy play of the various parts of the body is further diminished. From the uneasiness and constraint experienced in the feet, sympathetic affections of a dangerous kind often assail the stomach and chest; as hemorrhage, apoplexy, and consumption. Low-heeled shoes, with a sufficiency of room for the toes, would completely prevent all such consequences.

An improved taste in the male sex has long since abolished the coarse and self-annoying absurdity of

leathern small-clothes; but it is still too common to impede the circulation and the play of the muscles by tight apparel, especially in the regions of the stomach and neck. The immediate effect of these injudicious appliances is much inconvenience: the remote result is a diminution of the general strength and health. But all the errors of the male sex sink into insignificance when compared with one to which the fair are liable. In the construction of the human chest, nature has provided ample room for several important viscera, the functions of which cannot be in any degree disturbed without a wrong being inflicted upon the whole system. Here reside the heart, the lungs, the liver, and the stomach. Fine ladies may affect to shut their mind's eye to the existence of such things; but the daintiest of their emotions depend upon the right state of those very viscera, without which they could no more think, speak, and act, than they could cast languishing looks without eyes, or melt our hearts by witching minstrelsy without a tongue and fingers. In order to reduce themselves to an ideal standard of girth, almost all the unmarried, and not a few of those who are otherwise, brace themselves in a greater or less degree with corsets, which produce the desired roundness and slenderness at the expense of all the internal organs upon which health depends. The false ribs are pressed inwards; the respiratory and circulatory systems are crushed and thrust out of their proper place; the alimentary system is deranged; and even upon the exterior of the person, deformities of the most glaring kind, such as humped shoulders and curved spines, are produced. Custom to a certain extent enables the victim to endure the inconvenience: there are even some who feel so little trouble from it, as to deny that any harm ensues from tight-lacing. But a violation so excessive cannot be otherwise than mischievous. We have seen a young lady's sash which measured exactly twenty-two inches, shewing that the chest to which it was applied had been reduced to a diameter—allowing for clothes—of little more than seven inches!

All who are aware of the internal organs at that part of the body, know very well that it is impossible for these to exist in their natural condition within so small a space. Bruised, impeded, and disordered, they must of course be, and accordingly cannot fail to become a source of dreadful suffering to the wretched being who outrages them. Palpitations, flushings, dyspepsy, determination of blood to the head, and consumption, are among the evils which physicians enumerate as flowing from this sacrifice to vanity. Another of a moral kind is acknowledged to be of by no means infrequent occurrence: in order to soothe the painful sensations produced by the constraint, spirituous liquors and cordials are resorted to, and thus habits of the most degrading nature are formed. Another evil still, respecting which a hint may be sufficient, is the unfitting of the system for the duties of a mother. How many domestic afflictions, which are submitted to in a spirit of resignation, as the unavoidable decrees of Providence; how many of the saddest scenes which this world ever presents—gentle and tender girls pining away under the eyes of hopeless parents—beloved wives torn from the arms of husbands and children at the very moment when prolonged life was most needful—must be owing to a cause too trivial and unworthy to be mentioned in the same sentence with its so dire effects! No doubt, it is well to submit meekly to such afflictions; but while they are ascribed in all humility to a Providence which is upon the whole only another term for Mercy and Justice, let us not be blind to the fact, that they accrue through violations committed by ourselves upon laws established by Providence for our happiness, and might have been avoided by a different course of conduct.

The fashion of tight-lacing obviously owes its origin to a desire on the part of the ladies to attract admiration. It is of little importance to point out that they are quite wrong in their calculations as to the effect; but we would press upon the guilty parties, and all interested in their welfare, that tight-lacing is a practice which cannot be long persisted in without the most disastrous consequences. It is painful to reflect that in some instances, parents, so far from discouraging the practice, are so ignorant as to force it upon their children. We have heard of a young lady whose mother stood over her every morning with the engine of torture in her hand, and, notwithstanding many remonstrative tears, obliged her to submit to be laced so tightly as almost to stop the power of breathing. The result is, that the unfortunate victim is now severely afflicted with asthma, and has fallen into a state of low health. As a general rule, it cannot be too strongly impressed upon those who have the care of young persons, that all clothing should sit lightly upon the figure, so as to allow of the full play of every part of the system.

INNOCENT ENJOYMENTS.

A sufficiency of innocent enjoyments has been set down as the sixth requisite towards the preservation of health. It may seem almost superfluous to treat this part of the subject, since the disposition to take amusement is one by no means generally wanting. A regard, however, for the completeness of our little treatise, induces us to make a few remarks on it; and we are not satisfied that there is not a considerable number of persons to whom an injunction to take innocent enjoyments is needful. There may be some advantage, therefore, in seeing the matter placed on something like a philosophical basis.

No physiological doctrine seems more entitled to faith and regard, than that a harmonious exercise, in moderation, of all parts of the system, including the organs of the mental faculties, is necessary for health. It is proved by the very craving which we experience, after a long task, or a long perseverance in some particular habits, for something which will engage a different set of faculties. There is nothing which will pleasingly engage our thoughts for any considerable length of time. Something inferior will invariably be preferred, if it only be new. Now, the duties by which men in general earn their subsistence, are in all cases of such a nature as only to call into exercise a part of their mental and bodily system. Something is required at once to soothe and compensate us for the drudgery of our current labours, and to bring into exercise those parts of our muscular frame and intellect which professional duty has left unoccupied. To begin with a humble illustration: how delightful to a tailor, after long exercising his fingers and arms alone at his business, to enter into some athletic sport upon the village-green, by which his limbs also will be exercised! After a lawyer has fagged for a day at a brief, how delightful to be able, by the reading of a new novel or play, to call up another set of the intellectual powers! In these changes from grave to light occupation, there is at once repose given to the tasked faculty, and the gratification of employment given to others which have been pining for want of something to do. It so happens that, from the sentient nerves being mixed with those which direct the operations of all our organs, each organ has a sense of enjoyment in being rightly exercised. Even the stomach has, from this cause, a gratification when its functions are going on well, and this altogether independent of any pleasure we may have had in eating the meal upon which it is now employed. An organ left long unoccupied is thus somewhat like a child in a family which its parents have been overlooking. It craves to be noticed like the rest, and when the desired notice at length comes, it experiences a high degree of satisfaction. In short, variation of occupation and pursuit, for the purpose of keeping all the parts of the system in harmonious exercise and in healthy tone, is

one of the most important principles concerned in the preservation of health.

There are several powers of the mind which must have been designed for the express purpose of creating and receiving amusement, and the existence of which, therefore, shews that amusement has a place in the right economy of human life. The imitative arts in general—music, fiction, drollery of all kinds—spring directly from primitive faculties of the mind; and when we see the pleasure they give in society, we cannot doubt that they are things naturally required by man, and in which it is quite legitimate for him to indulge within moderate bounds and in circumstances compatible with innocence. These things are doubtless designed to alleviate the burdens of life and beguile us of its cares. They furnish something like a different sphere of existence, into which we may enter and temporarily lose the sense of all that harasses us in the ordinary one. The *joculator*—under which name our ancestors associated the poet, tale-teller, and mimic, and which we may apply equally extensively to the poet, novelist, artist, and player—is therefore a most useful functionary in society. We say nothing on the present occasion of the refinement to be derived, in addition, from communion with the productions of the higher class of such minds.

Amongst amusements, *reading* takes a most distinguished place; for there is none which may be more readily or more innocently indulged in, and fortunately, in our own country, it is one which may now be enjoyed by all. It is unquestionably the chief of indoor amusements; and few scenes are calculated to awaken more agreeable feelings in a well-constituted mind, than a family group assembled in their parlour, to hear some one of their number reading a pleasant book. Ever honoured be the great masters of fiction, who have allowed us, by these means, to pass from common life, for a time, into 'the tale of Troy divine,' the story of 'the gentle lady married to the Moor,' the tear-compelling fate of Ravenswood, and all the other numberless suppositions of things done, and persons who spoke and acted, which we feel to be more real than much of even the life that is passing around us!

Next to reading stands *music*, a means of enjoyment of which only a few comparatively, in our country, take advantage, but which might easily be made much more extensively available, and probably will be so in the course of a few years. Connected intimately with music is *dancing*, which is not only a cheerful amusement, but a positive and direct means of bodily exercise. A family musical or dancing scene, like a family reading scene, is a thing beautiful to look upon. There is a prejudice against both in some minds, on account of their being liable to abuse; but the abuses of both arise very much from their not being extensively or freely indulged in. Were music the general accomplishment which it might easily be made, it would not only be indulged in on all occasions with simplicity and innocence, but it would supplant coarser and more clandestine amusements. Dancing is the nightly amusement of the French peasantry, and it has never been pretended that these people are less virtuous than the corresponding class in our own country. *Theatrical representations* it might be more difficult to place on such a footing as to secure the unhesitating approbation of the good; but certainly if this were done, they might prove highly serviceable in furnishing amusement.

In the class of amusements, we must reckon meetings or promenades in ornamental grounds, excursions into the country, and little tours, all of which are highly commendable in those who are able to indulge in them. The entertainment of little parties of friends, and the going out to entertainments given by them in return, are other means of amusement common in society, and which may be moderately indulged in with much advantage. In short, whatever gives a pleasant variation to the monotony of life, without leading the mind away from duty or corrupting the manners, ought to be indulged in as freely as circumstances will permit. The mind returns from such diversions with renewed tone and power, and neither the time nor the expense is lost in the long-run. It is the more necessary to impress these maxims, as many well-meaning persons, alarmed perhaps at the occasional abuse of such enjoyments, repudiate them nearly altogether, and thereby lower the tone of their health, both as respects the body and the mind. It is particularly distressing to see such persons exercising a control over the young, and denying to their unfortunate protégés an element of life not much less pressingly necessary than the air they breathe. (See INDOOR AMUSEMENTS.)

Dr Southwood Smith, in his excellent work, *The Philosophy of Health*, has pointed out that pleasure is the ordinary, and pain in all cases an extraordinary, result of the action of our organs. 'There are,' he says, 'many cases in which pleasure is manifestly given for its own sake; but in no case is the excitement of pain gratuitous.' Pain is always a punishment; and, when it reaches a certain extreme, it is destructive of what feels it. But 'all such action of the organs as is productive of pleasure is conducive to the perpetuation of life. There is a close connection between happiness and longevity. Enjoyment is not only the end of life, but it is the only condition of life which is compatible with a protracted term of existence. The happier a human being is, the longer he lives; the more he suffers, the sooner he dies: to add to enjoyment, is to lengthen life; to inflict pain, is to shorten the duration of existence.' It may fairly be presumed, then, that a certain amount of enjoyment in life is necessary for health, and that when the quantity actually secured is much below that point, unhealthy conditions must ensue. If, for example, poverty or embarrassed circumstances press so severely upon a cautious and conscientious man, as to leave him scarcely a moment's comfort from one year to another, he cannot fail to sink in health. If married to a female of bad temper, or who afflicts him by bad habits, and if, from these causes, he rarely enjoys a moment of happiness, so also must his health fail. In short, to be placed in any such circumstances as constitute a bar against nearly all enjoyments, must prove injurious, and tend to the shortening of life.

Enjoyments are of many kinds. Some are sensual, as the taking of agreeable food; others are intellectual, as agreeable music, reading, &c.; others are moral, as the exercise of philanthropy, the religious feelings, &c.; and some are sympathetic, and consist in the exercise of the affections, and the reflection of that gratification which we have endeavoured to impart to others. We may consider as such all things over and above the plainest unrelished fare, and the supply of water, air, and a barely sufficient temperature. These are usually considered as strictly the *necessaries* of life, the others being the comforts or luxuries. The distinction is not quite correct. The first class are certainly immediately necessary to the support of life; that is to say, they are hourly, daily necessary. But more or less of what are called the comforts of life are also necessary, if we would preserve health. The only difference is, that the want of them would not tell in so short a time as the want of the so-called necessaries. If a human being be shut up in a cell, and allowed only a sufficiency of unrelished and unvaried food, with air and water, the want of all the enjoyments of life, sensual, intellectual, moral, and sympathetic, will, in a certain time, make him utterly miserable; the health of body and mind will give way; and if the experiment be sufficiently protracted, he will perish. The ignorance which prevails on this point has led to the trial of what is called the *silent system* in prisons, which is now about to be abandoned as utterly irreconcilable with humanity. It were well if more knowledge prevailed on the subject, for, from erroneous

ideas of what is *necessary* for healthy life, many deprive themselves or others of things which, when we take the element of time into account, are as essential to health as the supply of the air we breathe. There is, in some enthusiastic minds, a spirit of asceticism and self-mortification which would give up all the enjoyments of life together. Such persons rarely fail to reduce their own health, if they do not also exercise some unhappy control to the same effect over their fellow-creatures. While self-denial for moral purposes is always admirable, and over-indulgence of every kind saps the vigour and fortitude of the human character, it should be ever kept in view that there is great danger in reducing the allowance of comforts and indulgences too low. Very rigid views of what is necessary for the support of life usually prevail, wherever the affluent have to dictate a style of living for the poor. The tendency there is, to reduce allowances as nearly as possible to what may be called the *immediate necessaries;* for it does not seem just or right that paupers, adults or children, should enjoy any species of gratification. But these are short-sighted views. The health of these unfortunate persons requires something more, and this something would be granted by an enlightened humanity. We have a strong manifestation of this need in the eagerness with which paupers generally desire allowances of tea or tobacco, or, indeed, the least variation of their diet. The craving for these luxuries is not so much, what it is generally thought solely to be, the result of bad habits long indulged in, as it is the expression of a want in the personal economy —a want which, by one means or another, must be supplied, or injurious consequences will ensue.

Exemption from Harassing Cares.

It is little more than a repetition of doctrines already laid down, that, for the due preservation of health, a human being requires an exemption from acute distress of mind and harassing cares.

Mental distress and anxiety operate through the brain upon the condition of the whole body, and, when long protracted, effectually undermine the health. 'It is impossible,' says Dr S. Smith, 'to maintain the physical processes in a natural and vigorous condition, if the mind be in a state of suffering. Every one must have observed the altered appearance of persons who have sustained calamity. A misfortune, that struck to the heart, happened to a person a year ago: observe him some time afterwards—he is wasted, worn, the miserable shadow of himself; inquire about him at the distance of a few months—he is no more.' It is Dr Smith's opinion, that the nearest cause of many suicides is not strictly a desire to escape from a state of suffering, but some disease, probably inflammation of the brain, brought on by distress of mind. 'By a certain amount and intensity of misery, life may be suddenly destroyed; by a smaller amount and intensity, it may be slowly worn out and exhausted. The state of the mind affects the physical condition; the continuance of life is wholly dependent on the physical condition; it follows that, in the degree in which the state of the mind is capable of affecting the physical condition, it is capable of influencing the duration of life.'

Depression of mind, besides its immediate effect on the nervous system, deranges the respiration, and mars the proper oxygenation and circulation of the blood. A diminished vitality is the consequence, often leading to pulmonary consumption. An excessive agitation and alarm of the selfish feelings, such as takes place in some minds on the approach of an epidemic, affects the whole system in such a way as—to use an expressive phrase of Dr Combe—'places it on the brink of disease;' and hence the notoriously great liability of persons in this state of alarm and apprehension to fall victims to the malady when it comes. It has been remarked that an army in a high state of confidence and cheerfulness after a victory, has a much smaller proportion of sick than in the opposite circumstances, or even in its ordinary condition. The usual proportion of sick in a garrison quartered, during peace, in a healthy country, is five per cent.; during a campaign, when there is more anxiety of mind, it is ten; in the event of defeat, although the circumstances be otherwise not unfavourable, the proportion rises to a much higher amount. It is a very instructive fact, that in a large detachment of the French army cantoned in Bavaria immediately after the battle of Austerlitz, the proportion of sick was little more than *one* per cent.

GENERAL OBSERVATIONS.

The fundamental principle of every effort to improve and preserve health has been thus stated: 'Man, as an organised being, is subject to organic laws, as much as the inanimate bodies which surround him are to laws mechanical and chemical; and we can as little escape the consequences of neglect or violation of those natural laws, which affect organic life through the air we breathe, the food we eat, and the exercise we take, as a stone projected from the hand, or a shot from the mouth of a cannon, can place itself beyond the bounds of gravitation.' To this it may be added, that 'all human science, all the arts of civilised man, consist of discoveries made by us of the laws impressed upon nature by the Author of the universe, and the applications of those laws to the conditions—which are laws also—in which man and the particular bodies and substances around him are placed; nor, it is manifest, should any science concern us more than that which relates to the conditions on which organic life is held by each individual.'

The preceding sections are but explanations, such as we have been able to afford, of the conditions under which the organic frame of man exists, and the agencies, internal and external, which operate upon it, for the maintenance of health or the introduction of disease. It must be evident, where there is a conviction of the truth of the fundamental doctrine, that individuals and societies have their health very much at their own disposal; that a careful avoidance, on the one hand, of what is noxious, and a judicious attention to what is beneficial, are what are chiefly necessary for the preservation of the human frame in health to old age; and that premature deaths, over and above those which result from unforeseen casualties, instead of being, as supposed by the untutored mind, a mysterious and irreversible decree of Providence, are simply the natural effect of our own violation of laws which Providence has appointed for our welfare. It might still be objected that human nature is such, that the due obedience and observance of those natural ordinances are not to be expected; so that the vast quantity of disease, and the great number of premature deaths, which afflict our present state of being, are equally to be regarded as things immutable, and therefore to be tranquilly submitted to. But this view would be not less a mistaken one; for there is no fact more clearly ascertained, than that disease and premature death are not, and never have been, fixed at any given amount, but yield constantly to the power of any new conditions which man may be able to introduce. Regarding clear views on this subject as of great importance, we shall here enter a little into detail.

The object is, we apprehend, to shew that sickness and mortality vary both in place and in time, according to physical and organic conditions.

Inquiries into these subjects were not made in ancient times; but during the last two hundred years, such facts have been recorded as enable us to ascertain that in that space of time, with regard to nearly the whole of Europe, there has been a gradual improvement in health and life, in proportion to improved conditions. In Sweden, for instance, between 1756 and 1763, the annual mortality was, for males, 1 in $33\frac{1}{4}$; for females,

1 in 35¾; whereas in the year 1800 it had diminished to 1 in 34¾ for males, and 1 in 37½ for females. From mortuary tables preserved with considerable accuracy at Geneva, it appears that at the time of the Reformation, one-half of the children born died within the sixth year; in the seventeenth century, not until the twelfth year; in the eighteenth century, not until the twenty-seventh year; consequently, in the space of about three centuries, the probability that a child born in Geneva would arrive at maturity, has increased fivefold. In London, in the year 1606, the annual deaths were 1 in 14⅓, or 7 per cent. of the population; and in plague-years during that century it reached 25 in 100, or every fourth man, woman, and child! *In* 1838, *it was only* 1 *in* 35½. Knowing that, at the former period, the city was dense and ill-cleaned, and that the habits of the people were not then what they are now, we cannot doubt that this diminution of mortality to less than one-half is owing to the improved conditions in which human beings now live in the metropolis. Between the years 1730 and 1750, 74 of every 100 children born in London died before they were six years of age; but in more recent times, only 31 and a fraction out of every 100 die under the same age—that is to say, the deaths of children in London were then more than twice as numerous as they are now. About a century ago, the mortality of the children received into the London hospitals was of astonishing amount. Though the fact seems scarcely credible, we believe there is no good reason to doubt that, of the 2800 annually received, 2690, or *twenty-three in every twenty-four*, died before they were a year old. It was at length seen that this mortality was the effect of overcrowding, impure air, and imperfect aliment; and after an act of parliament had been procured to compel the officers to send the infants to nurse in the country, only 450 out of 2800 died in the first year. It has been ascertained that, during the last century, about a third has been added to the average expectation of life—that is to say, an individual now has as good a chance of living forty years, as he had a hundred years ago of living thirty. To what can such a fact be owing but to the diminution of the causes of disease in the improved conditions of the people?

The facts ascertained with regard to differences of mortality in different places are equally striking. A remarkable instance of the effect of marshes upon health is cited by M. Villermé. Formerly, the district of Vareggio, in Tuscany, was in this condition, and its few miserable inhabitants were every year visited by severe agues. In 1741, floodgates were erected to keep out the sea, the marsh was dried up, and ague appeared no more. Vareggio subsequently became a populous and healthy district. The Isle of Ely is a marshy district in the east of England, and it was ascertained that of 10,000 deaths which occurred in it between the years 1813 and 1830, no fewer than 4732 were of children under ten years of age; the proportion of deaths of children under ten in all the other agricultural districts of England being only 3505, or as about 3 to 4 of the former number. Of 10,000 deaths between ten years and extreme old age in the same period, there were, of persons between ten and forty, 3712 in the Isle of Ely, and only 3142 in drier districts. There are some remarkable discrepancies of mortality in different counties of England. While the proportion of annual deaths in every hundred persons under six years of age is, for the whole of England and Wales, about five and a third, the proportion in Suffolk is three and a half; in Warwick, six; in Middlesex, eight and a third. Suffolk is an agricultural county; Warwick contains Birmingham and some other large towns; and the metropolis is situated in Middlesex: can we resist concluding that the pure air and constant exercise which children obtain in the country are the immediate means of prolonging their lives; while the narrow accommodations, impure air, and limited exercise to be had in large towns have exactly the contrary effect? In the general population of England, it was a few years ago ascertained that 443 in 1000 die under ten years of age; but in Manchester and Salford the number was a third larger, or 602. Here, the miserable circumstances of many of the humbler classes in Manchester—above eighteen thousand of them, for one thing, then living *in cellars*—must be considered as the immediate cause of the disproportioned mortality. While, in 1838, the general mortality of London was, as stated, 1 annually in 35½, there were great differences with respect to different districts. In Camberwell, an open suburban district, it was 1 in 52; in Hackney, a similar district, 1 in 54; but in the huddled district of St George's, Southwark, it was 1 in 30; and in the still more dense and miserable region of Whitechapel, so much as 1 in 26, or exactly double the mortality of Camberwell.

In a late public document, we find an investigation which brings out an interesting contrast between densely and thinly peopled districts of the entire kingdom of England. 'In three districts, the annual mortality during ten years previous to 1851, was at the rate of 15 deaths in every 1000 living; in fourteen districts, at the rate of 16; in forty-seven districts, at the rate of 17 in 1000 living. Where the mortality rate was 15, 16, and 17, the average number of persons living on 100 acres was respectively 9, 17, and 22. Again, the annual mortality in the same period in thirteen districts was at the rate of 27 deaths in 1000 living; while in eighteen districts the rates ranged from 28 to 36 in 1000 living. The number of persons on 100 acres in these districts was, respectively, 279 and 693.' The connection of density of population, always attended as it is by misery, with large mortality, is thus clearly shewn.*

It is also now ascertained that England is more healthy than any continental country, the next to it in this respect being France. In continental cities, the annual rate of mortality is seldom less than 30 in 1000, and the rate frequently rises to 40 in 1000. In London, the rate of mortality in 1856 was estimated at 25 in 1000.†

Taking the whole of the above facts into account, we must see that not only do health and longevity depend expressly on laws the operation of which we can understand, but man has it in his power to modify to a great extent the circumstances in which he lives, with a view to the promotion of his organic wellbeing and preservation. We see that the draining of a marsh banishes the ague, that a change from city to country air diminishes mortality, and that the greater comforts possessed by the affluent secure them longer life than the poor. It may not immediately be in the power of every one to change his circumstances from the unhealthy to the healthy; but it is a great matter to know that the object is within human power, for then at least an encouragement is held out to induce each individual to make every possible effort to put himself, and to contribute to putting society in general, into more salubrious conditions.

The object may be said to depend partly upon individual, and partly upon social efforts. Every person has some control over the quantity and quality of the food he eats, the condition of the air he breathes, and the exercise, repose, and recreation which are demanded by his muscular and nervous system, according to the principles laid down in this and similar treatises; as also some power to refrain from injurious excesses, and to avoid the various external agencies of a detrimental kind which constantly beset him. Let him act as he ought to do in these respects, and he will reap an

* Document quoted in *Companion to Brit. Almanack* for 1857, p. 161.

† Registrar-general's Quarterly Return, 1856, No. 30.

immediate reward in that pleasurable state of consciousness which attends a healthy existence. But some of the most important requisites for health depend on public measures. The amount of the necessaries and comforts of life to be obtained by the great mass of the operative classes in all countries, depends very much upon regulations which may have been made with regard to *production* and *exchange*, as also those which may have been made for instructing and morally elevating and sustaining the bulk of the people. It unfortunately happens, in most countries, that while the bearing of certain acts upon individual happiness is fully seen and provided for, those which affect the condition of communities are imperfectly understood; so that measures destructively injurious to millions will be blindly enforced and defended by those who would severely punish the slightest wrong inflicted by one man upon another.

Measures for improving general conditions, with respect to air and exercise, are perhaps more readily practicable; yet here also the bearing of active principles upon great masses is so dimly seen, that, not to speak of more positive difficulties, it is usually long before proper sanitary regulations are made. The cleaning police of most cities is certainly improved considerably within the last fifty years; yet it is still far from being what it ought to be, while drainage continues to be extremely defective, and ventilation and means of innocent and healthful recreation can scarcely be said to be thought of. Some facts elicited by recent parliamentary inquiry, with regard to several of our principal cities, are of a most startling kind.

Dr Arnott, when examined as to the prevalence of fever in Bethnal Green, Whitechapel, Wapping, and certain other districts in the metropolis, attributed them directly to the dirty and neglected state of these localities, instancing—'Houses, courts, and alleys without privies, without covered drains, and with only open surface-gutters, so ill made, that the fluid in many cases was stagnant; large open ditches containing stagnant liquid filth; houses dirty beyond description, as if never washed or swept, and extremely crowded with inhabitants; heaps of refuse and rubbish, vegetable and animal remains, at the bottom of close courts and in corners.' [The amount of noxious matter which is allowed to collect in London is far beyond what most of its inhabitants have any conception of, as is the case with most other conditions chiefly affecting the poor.] In Manchester, 18,300 persons, or one-twelfth of the whole working population, live beneath the level of the ground, with an insufficiency of both light and air. In that town, the dwellings of labourers are often situated in narrow courts, and back to back, so as to prevent ventilation; the drains are far from sufficient; and till recently, there was not in the town one free space in which the people could enjoy the slightest recreation. In Liverpool, 39,000 persons live in cellars, dark, damp, confined, ill ventilated, and dirty. The class next above, to the number of 80,000, inhabit houses built around small courts, closely pent up, back to back, with only one entrance to each, and usually a receptacle for refuse in the centre—an arrangement which appears as if it had been expressly calculated to keep health low and mortality high. In Leeds, a similar style of building obtains, with a similar train of circumstances —'no effective drainage, inspection, or system of paving or cleansing.' The greater part of this town was described in 1839 as 'in a most filthy condition, demanding an immediate remedy.' It was mentioned, that in a certain dirty yard there was a house which for many years had been the seat of disease of a very malignant character: three years ago, the attention of the commissioners of police was directed to the extremely imperfect drainage of the surface-water: at that time, a better escape for the refuse-water was provided; and since that period, says the reporter, 'I believe *we have not had a single case of fever from that particular locality*.'

Narrow alleys and close courts, with wet filth constantly exhaling within them, and containing a densely huddled and extremely poor population, exist in Edinburgh, where, however, an exposure to high winds makes the evil less pestilential. In Glasgow, a comparatively level city, the same peculiarity exists to perhaps a greater extent than in any other British city. This, added to the miserably insufficient succour extended to the poor, and the influx of migratory Irish, renders Glasgow at present one of the unhealthiest cities in Europe; the mortality of the year 1837 being 1 in 24½, and the number of fever cases for the five years before 1839 at an average of 11,118 per annum. Here also we have a most notable instance (see No. 30, p. 473) of the counteractive power of a single sanitary principle; for a house containing about five hundred poor inhabitants, having been ventilated by a draught from each room in 1832, fever, which had previously never been absent from that dwelling, was nearly banished, only four cases occurring in the ensuing eight years, though fever raged during that period in all the other districts of the city occupied by the poorer classes.

The Larder.

FOOD—BEVERAGES.

IN the preceding sheet, we have shewn that man is destined to subsist on a mixed diet—that is, partly on vegetable and partly on animal food; and we shall now proceed to describe the specific characters of the more common alimentary substances, in as far as these have been determined by science and experience. In so doing, we shall consider their natural history and production, their chemical composition, their relative alimentary value, and the like, leaving their culinary preparation for the subject of a separate treatise. Before doing so, however, it will be necessary to establish a clear conception of the functions which food has to perform in the animal economy.

Chemical research has shewn that the food of man is composed of organic matter, water, and mineral ingredients. The mineral ingredients are required to form the skeleton or solid framework; the watery fluid is necessary to the due performance of the vital functions; whilst the organic matter supplies at once the heat and nourishment of the system. Every one knows how indispensable animal heat is to the preservation of life and health; and this heat is produced, according to the researches of Liebig and others, by the consumption of a certain portion of the food, much in the same way as fuel produces heat by being burned in our fireplaces. The elements of this portion of our food are hence termed *calorifiant*. They are also termed *respiratory*, because it is chiefly by the act of respiration that they, after having undergone various changes in the body, are brought in contact with the oxygen of the atmosphe in the lungs and capillaries (small blood-vessels) a over the body. Animal heat is thus generated by combination of the carbon and hydrogen of a portic of the food with the oxygen of the inspired air—he always being given out by such chemical changes, ar compounds of carbonic acid and water being the resul which are given off by the lungs and skin as was matter. The elements of the other portion of our foc are termed *nutritive*, because they supply the was and growth of the fabric. Every thought of the min every act of the body, changes a portion of the livir particles of our systems to dead and waste particle which, being no longer of use, are either burned by tl slow combustion already described, or carried off a excrementitious matter; and it is the province c the elements of nutrition, by going to form blood, t renew the parts where such waste has been produce The leading ingredient in the nutritive portion i nitrogen or azote; hence the terms nitrogenous c azotised are equivalent to nutritive.

From the preceding statements, it must be evider that all wholesome dietary must contain both a *hea forming* and a *flesh-forming* principle; and that, accorc ing as we live in a hot climate or cold climate, tak much exercise or remain sedentary, so must we hav recourse to food which will supply the elements whic our bodies most stand in need of. It is the province c chemistry to determine the real constituents of huma food, and to point out in what the various articl commonly used are excessive or defective; and thi

attempts have recently been made to classify substances according to their capabilities of supplying heat, flesh, and bone.

The following table gives the relative proportions of *heat-producing* and *flesh-forming* ingredients in various articles of diet:

		Flesh-Forming.	Heat-Producing.
Cow's Milk	contains, for	10	30
Human Milk	" , "	10	40

In whatever way the results may be stated, it is necessary that they be obtained with accuracy; and it is equally necessary that the condition of the body as to health or disease, rest or exercise, shelter or exposure to cold, should be also ascertained; so that, by the adoption of a proper diet, any defect may be supplied, or excess corrected. On this point, man has yet made little true scientific progress. Where he has arrived at the truth, it has been chiefly by a long process of trial and error; and it is only now that he is beginning to apply the lights of science to guide and direct him. In describing the various articles of food—vegetable and animal—we can therefore only refer to very general results: accurate and detailed experiments being yet in many instances altogether wanting. To Baron Liebig, Boussingault, Mulder, and other continental chemists; to our own countrymen, Sir Humphry Davy, Professor Johnston, Drs Thomson, Pereira, and Playfair, are we indebted for most of those researches on food which bid fair to introduce a system of dietetics, if not altogether new, at least more strictly in accordance with sound reason and economy. It must not be supposed, however, that substances which yield to the chemist the largest amount of nutritive matter, are in every case the most nutritious and wholesome. The fact is, they may contain other principles which greatly impair their digestibility, or they may be unfitted for peculiar states and conditions of health; or, what is also possible, they may be obnoxious to certain constitutions, unless administered along with the necessary correctives. Due allowance must ever be made for such exceptions; and all that we can reasonably expect of the chemist or physician, is a statement of results as applicable to healthy or normal conditions.

FOOD.

The aliment of man consists of solid and liquid substances; hence such popular distinctions as 'meats and drinks,' 'food and beverages'—the one calculated to allay the cravings of hunger, and to afford the body substantial support; the other simply to allay the sense of thirst. Such distinctions, however, are more popularly convenient than scientifically correct: milk, for example, though liquid, being the sole support of the young mammal, and affording, moreover, more substantial nourishment to every portion of the fabric than any solid substance whatever; while starch, though solid, yields little or nothing that can administer to the growth of the living tissues. Adopting, however, the common distinction of 'food and beverages,' as in some measure convenient, we shall treat the former under the three heads—*vegetable*, *animal*, and *mineral*—remarking that it is chiefly the vegetable and animal kingdoms (and especially the vegetable) from which man derives the greater portion of his solid sustenance. In the dietary of tropical countries, the vegetable element generally prevails over the animal; in temperate regions, the proportion is more equable; while in the colder latitudes, the flesh of animals may be said to be the staple of existence.

VEGETABLE FOOD.

Vegetable food, wherever employed, is consumed partly in a green and succulent state, either cooked or uncooked; partly in a ripe condition—as fruits, nuts, and the like; and partly when dried and artificially prepared—as the various bread-corns. In whatever condition or form vegetable substances may be used, they consist essentially of the same elements—carbon, hydrogen, oxygen, and nitrogen, with a small proportion of sulphur, phosphorus, and earthy salts. These are usually termed *ultimate* elements, from which the living vegetable elaborates certain *proximate* principles for the construction of its own peculiar fabric. These principles are—starch or fecula, gluten, vegetable albumen, sugar or the saccharine principle, gum or mucilage, lignin or woody fibre, vegetable jelly or pectin, fixed and volatile oils, wax, resin, balsams, gum-resins, camphor, tannin, and colouring matter. Of these, the most abundant are starch, gluten, albumen, sugar, and gum: these constitute the principal ingredients in all esculent vegetables; and it may be remarked, that starch and gluten are the most important as regards quantity—starch yielding carbon, or heat-forming, and gluten, nitrogen, or flesh-forming matter. It may also be observed, that some of these proximate principles are convertible, or nearly allied: thus starch can be converted into sugar by the processes of vitality and fermentation; and albumen hardly differs from gluten. According to the prevalence of these respective principles, writers on dietetics have proposed certain classifications of vegetable food, such as the starchy or amylaceous, the saccharine, mucilaginous, oily, and so forth. Others, again, finding that many plants yield several principles in equal abundance, and that it is impossible to draw such distinctions without leading to misconceptions, abandon this classification, and merely treat of the parts consumed, as the seeds, roots, fruits, leaves, and the like. Any rigid division of this kind is also liable to objection, since the seeds of a plant may be wholesome, while its roots are poisonous; or its leaves may be worthless, while its fruit is valuable; or it may contain a deleterious principle when raw, and yet be exceedingly wholesome and agreeable when boiled or roasted.

One of the most abundant sources of vegetable food is the cereals, or bread-corns—wheat, rye, barley, oats, millet, and maize—all of which belong to the natural order *Graminaceæ*, or grain-bearing plants. All of these grow in a similar manner; all yield starch, gluten, and a certain amount of phosphates; and all have been cultivated and improved by the inhabitants of different countries from time immemorial. They are commonly spoken of as *farinaceous* foods; their elements of *nutrition* being albumen, fibrin or gluten, and casein; and their elements of *respiration*, starch (principally), sugar, oil, and gum.

Wheat (*Triticum*), of which there are numerous varieties, justly stands at the head of the cereals. It is now grown largely in all civilised countries, and forms a principal portion of human food. The grain, freed from its bran or husk, is usually ground to a fine *flour*, and in this state is used in the manufacture of bread, pastry, macaroni, vermicelli, semolina, and other preparations. It consists, as already stated, of starch, gluten, sugar, gum, certain salts, and water; and these ingredients are

found to vary, not only with the soil in which the corn is grown, but according to the climate or latitude—that of Southern Europe yielding from two to six per cent. more gluten than that grown in the north. It is for this reason that Italian flour is so well fitted for the manufacture of macaroni; and that bakers often prefer a mixture of wheats in the composition of their loaves. The following are given as analyses of different wheats and wheat-flours:

	French Wheat.	Odessa Hard Wheat.	Odessa Soft Wheat.	First Flour.	Second Flour.
Starch, .	71·49	56·50	62·00	71·2	67·78
Gluten, . .	10·96	14·55	12·00	10·8	9·02

Bran, .	—	2·30	1·20	—	2·00
Water, . .	10·00	12·00	10·00	8·0	12·00

Bread is the most important article of consumption prepared from the flour of wheat, and may be fermented or unfermented.

1. Common *fermented* or *loaf-bread* consists of wheat-flour, salt, water, and either yeast or leaven (old dough already in a state of fermentation). To these, bakers occasionally add potatoes and alum—the former to assist the process of fermentation, and render the bread lighter; the latter, to augment its whiteness and firmness. As to the addition of potatoes, there can be no objection beyond the substitution of an article containing no true nutritive matter; but as to alum, it is highly objectionable, and its use by bakers is accordingly prohibited by law. The rationale of the fermenting process is this: 'The yeast or leaven causes the flour to undergo the vinous fermentation, by which carbonic acid and alcohol are formed. The carbonic acid is prevented from escaping by the tenacity of the dough, which, becoming distended with gas, swells up, and acquires a vesicular structure, forming a kind of spongy mass. In this way, therefore, are produced the vesicles or eyes, which give to ordinary loaf-bread its well-known lightness and elasticity. If the vinous fermentation be not checked in due time by *baking*, the dough becomes sour; and for this purpose, the mass, after being formed into loaves, is exposed in an oven to an elevated temperature, which puts a stop to the fermentation, expands the carbonic acid, expels the alcohol formed, and drives off all the water capable of being removed by the degree of heat employed. On weighing bread taken from the oven, it is found to be twenty-eight or thirty per cent. heavier than the flour used in its preparation.' 'In the formation of wheaten bread,' says Sir Humphry Davy, 'more than one quarter of the elements of water combine with the flour; more water is consolidated in the formation of bread from barley, and still more in that from oats; but the gluten in wheat being in much larger quantity than in other grain, seems to form a combination with the starch and water, which renders wheaten bread more digestible than other species of bread.' From pretty accurate experiments, it has been found that the proportion of nutritive to the heat-forming principle in loaf-bread is as 10 to 46; in milk, the natural food of all young mammalia, the proportion is as 10 to 40.

With regard to the other common forms of fermented bread, Dr Pereira, in his valuable Treatise on Food, has the following remarks: 'The *fine bread* prepared from flour only is the most nutritive and digestible. *Brown bread* made from wheaten meal, which contains bran, is laxative, and is used with effect by persons troubled with habitual constipation, as well as by those labouring under diabetes. *Hot rolls* are indigestible, and unfit for dyspeptics and invalids; indeed, all kinds of new bread are injurious. Rolls, both English and French, are made with a much larger proportion of yeast than is employed in ordinary bread. The different kinds of *fancy breads* are less adapted for the use of invalids, and of those who suffer from a tender stomach, than the common loaf-bread. *Compressed bread*—that is, bread which has been submitted to compression by the hydraulic press—becomes dry and hard, and may be kept for an almost indefinite period; it requires to be granulated before being used. *Rusks*, and *Tops and Bottoms*, are both made with wheat-flour, butter, sugar, and milk, and a considerable quantity of yeast to give them lightness.'

2. *Unfermented* or *unleavened bread* is prepared in two forms—either heavy and compact, or light and spongy. The former condition is that in which all the varieties of biscuits appear—the main ingredient in these being flour worked into dough with hot or cold water. *Sea-biscuits*, so largely employed in the victualling of the navy, are composed of wheaten flour and a little bran: they are hard and heavy, and are difficult of mastication. *Biscuit-powder* is not of course liable to this objection, and being prepared for use with hot water, is reckoned fair food for infants. The *captains' biscuits* of the ships are generally made of fine flour with a small proportion of butter; the so-called *Abernethy biscuits* are made variously by different bakers—most of whom add a little yeast, and flavour with caraway-seeds. In the numerous *fancy biscuits* now used, butter, milk, sugar, and the like, are indispensable ingredients; and for this reason, little definite or favourable can be asserted of their dietetic properties.

The other form of unfermented bread is that in which, by the use of effervescing compounds, it is rendered light and spongy, and made to resemble ordinary loaf-bread. Numerous receipts have been given, and several patents taken out, for the manufacture of this species of bread, but all of them may be readily comprehended from a description of the original method. It is well understood, that if we take hydrochloric acid and carbonate of soda, and mingle them in due proportions, an effervescence will take place, carbonic acid is disengaged, and common salt (chloride of sodium) is formed. Now, if we take the carbonate of soda and hydrochloric acid, and knead them as rapidly as possible with dough, an internal action will go on, the carbonic acid gas will raise the mass, the salt formed will season it, and, if properly baked, a light, sweet, and nutritious bread will be the result. Such is the rationale of all the unfermented breads now so largely in vogue; though of course various bakers have adopted various ingredients, and hit upon different modes of applying them. Wheaten flour, 7 pounds; carbonate of soda, 350 to 500 grains; water, 2¼ pints; and hydrochloric acid, 420 to 560 grains, are said to form an excellent bread. A still finer and sweeter bread is said to be prepared from the following proportions: Flour, 1 pound; supercarbonate of soda, 40 grains; cold water, half a pint, or as much as may be sufficient; hydrochloric acid, 50 drops; and powdered loaf-sugar, a tea-spoonful. According to Dr Robert Thomson of Glasgow, a good method of making unfermented bread is—to take of flour, 4 pounds; supercarbonate of soda, 320 grains; hydrochloric acid, 6 fluid drachms; common salt, 300 grains; and 35 ounces of water by measure. The soda is first mingled with the flour very intimately; the salt is dissolved in the water and added to the acid—the whole being then rapidly mixed, as in common baking. The bread may be either baked in tins or formed like cottage-loaves, and should be kept from one to two hours in the oven. Should it appear yellow, it is a proof that the soda has been in excess, and indicates the propriety of adding a little more acid—the acid varying somewhat in strength.

As to the merits of fermented and unfermented bread, the latter has the advantage in point of economy, there being no loss of nutritive principle through the destructive process of fermentation. The result of experiments upon the bread produced by the action of

hydrochloric acid upon carbonate of soda, has been that in a sack of flour there was a difference in favour of the unfermented bread of about seven loaves.

Among unfermented preparations from wheat-flour may be classed a large variety of *cakes*, *pastry*, and *pudding*. From the amount of butter, lard, eggs, fruit, seasoning, &c., which they generally contain, they form a most indigestible kind of food, totally unfit for children, invalids, and those having a tendency to dyspepsia. While these remarks apply to ordinary bakers' cakes, pastry, suet-pudding, and the like, there are certain light cakes, baked and boiled bread-puddings, which are not only agreeable, but wholesome and nutritious. The Italian preparations, *macaroni*, *vermicelli*, and *Cagliari paste*, consist of the finest wheat-flour. The first two have their well-known forms given to them by forcing the tenacious paste through a number of holes in a metallic plate; the latter is pressed into the form of stars, rings, Maltese crosses, and the like. The nutritive qualities of all these preparations, according to Pereira, are identical with wheat; and when plainly cooked, as by boiling (macaroni and vermicelli soup), they are easily digestible. *Semolina*, *manna-croup*, &c., are granular preparations of the finest wheat deprived of bran. They possess, of course, all the nutritious properties of wheat, and are very agreeable, light, and well fitted for children and invalids. The same remark applies to the so-called *farinaceous foods* of the druggist, which are either wheat, pea, or lentil flour subjected to some heating process which bursts the starch granules, or admixtures of one or other of these with that of barley or oats.

Barley (*Hordeum*), of which there are several varieties, cultivated in the British islands, is one of the cereals found all over the temperate regions of the northern hemisphere—some of the varieties coming to profitable maturity even within the limits of the polar circle. As a staple of human food in northern countries, it is used in various forms: thus, freed from their husks by milling, the grains form *pot-barley*, used for making broth; still more thoroughly freed from husky matter, and rounded and polished in the mill, they constitute *pearl-barley*, used also in broth, and sometimes boiled in water and eaten as rice with milk; the common pot-barley, ground to flour, forms the *barley-meal* of the Scotch; and from pearl-barley similarly treated is obtained the *patent barley* of the shops. In any of these forms, barley forms a wholesome and nutritious food.

The composition of barley has been stated by Einhof to be as follows:

THE RIPE SEEDS.

Meal,	70·05
Husk,	18·75
Moisture,	11·20
	100·00

THE BARLEY-MEAL.

Starch,	67·18
Fibrous matter (lignin),	7·29
Gum,	4·62
Sugar,	5·21
Gluten,	3·52
Albumen,	1·15
Phosphates of Lime and Magnesia,	0·24
Moisture,	9·37
Loss,	1·42
	100·00

In 100 parts Norfolk barley, Sir Humphry Davy found 79 starch, 6 gluten, 7 saccharine matter, and 8 husk. Proust, Vauquelin, and others have subjected this grain to analysis with very nearly the same results; and Dr Thomson adds that the gluten of barley is partially soluble in cold water, as is shewn in the steeping of the grain for malting; but it coagulates in 120° or 130°, and falls down in gray-coloured flocks. He also extracted from the husks of barley a small quantity of an oily matter, of an asparagus green colour, and taste resembling that of spirits from raw grain, to which no doubt the flavour of whisky is owing. Some persons who are habitually costive, derive advantage from the use of barley-meal cakes and porridge. We say cakes, for in consequence of the small quantity of gluten it contains, it is incapable of undergoing the panary fermentation, so as to form a light spongy loaf like flour from wheat. The barley *bannocks* or *scones* of northern countries are formed by kneading the meal thoroughly with water and a little salt, flattening the dough into cakes rather thin than otherwise, and toasting the same either on a hot iron plate (in Scotland, the *girdle*) or before a clear brisk fire. When new and properly made, bread of this kind is sweet and palatable; and though somewhat more difficult of digestion than wheaten bread, possesses the advantages already mentioned. *Barley-water*, or a decoction of pearl-barley, is reputed a soft and lubricating beverage, slightly nutritive, and very easy of digestion.

The Oat (*Avena*), of which there are also a number of varieties cultivated in Britain, is one of the hardiest of our cereals. It can be grown with advantage where neither wheat nor barley will ripen; and indeed thrives best under a cold climate like that of Scotland, if the soil on which it is planted be sufficiently dry. It cannot be cultivated in the south of Europe, and is altogether a staple for the inhabitants of high northern regions. The entire grain is largely used as food for horses; freed of the husk, it forms *groats* or *grits*, and these, when crushed, are termed *Embden groats*, and when ground to flour, *prepared groats*. In one or other of these forms, oats are pretty extensively used as human food; but more largely as *oatmeal*, which is prepared by grinding the kiln-dried groats to various degrees of fineness, according to taste. This meal is not so white as wheaten flour, and has a peculiar agreeable odour. In various districts of the country, it is used for making bread, porridge, puddings, and other preparations.

Four specimens of Scotch oats, on being carefully analysed, gave the following results:

	HOPETON OATS.			POTATO OATS.
	Northumberland.	Ayrshire.	Ayrshire.	Northumberland.
Starch,	65·24	64·80	64·79	65·60

From these data it would appear that oats are superior in point of nutrition to wheat; and experience proves that they form a substantial nutritive article of diet, since many of the labouring classes in Scotland, in Lancashire, Derbyshire, Northumberland, and other parts of England and Wales, subsist chiefly upon bread, pottage, and other oaten preparations. Oaten food, according to Pereira, is apt to disagree with those having a tendency to dyspepsia: in other words, it is apt to become acid on the stomach, and oat-bread, in particular, to occasion heartburn. With good digestive organs, however, and a proper amount of vigorous exercise, no inconveniences of the kind are experienced. *Porridge* or *stirabout*, which is composed of oatmeal, water, and a little salt, when well boiled, is one of the best forms in which oaten food can be taken, and partaken of with milk, constitutes a capital breakfast

Gruel is a mild, nutritious, and, in most cases, an easily digested article of food. On account of the nitrogenous principle which it contains, it is of course more nourishing than the starchy preparations (arrow-root, sago, tapioca, &c.) frequently employed in the sick-chamber. It may be prepared either from oatmeal or ground groats (Robinson's, for example), and may be sweetened with sugar, acidulated with lemon-juice, or spiced. Butter should never be added in the case of the dyspeptic, or where the stomach is tender. *Oaten-cake*, unless made with scalding water, and well fired, is apt to be heavy and heating.

Rye (*Secale cereale*), though cultivated to some extent on the light sandy soils of our country, can scarcely be considered as one of the staples of British consumption. The small amount grown, however, generally meets with a ready market, partly for distillation, and partly for the making of a light spongy bread, having a peculiar but rather agreeable flavour.

The composition of rye has been ascertained by Einhof and Boussingault, with the following results:

RYE-SEEDS.

	Einhof.	Boussingault.
Husk or bran,	24·2	24
Pure meal,	65·6	63·08
Moisture,	10·2	12·92
	100·	100·00

	100·00	100·

'The husk,' says Webster, in his *Cyclopædia of Domestic Economy*, 'possesses an aromatic and slightly acidulous flavour, which renders it agreeable to the palate. The bran should not, therefore, be entirely separated from the flour; for if the grain be ground fine, and divested entirely of the husk, the bread will be deprived of much of its pleasant taste. Rye-bread is consequently made of coarse flour, which, together with its dark colour, has probably given rise to much of the dislike to it in this country. The quantity of gluten which it contains accounts for the facility with which it may be fermented into spongy bread, which is not the case with oats and some other grains. But bread made of it very soon becomes sour, indeed it undergoes an acetous fermentation in the process of baking, and is thought to have a gentle action on the bowels. In some farmers' families, household bread is made of a mixture of one-third rye and two-thirds wheaten flour, which makes a sweeter bread than that solely of wheat, and is preferred to any other by those who are in the habit of using it. The bread is very firm and solid, and retains its juiciness and moisture long, being also very nutritious.' Though little used with us, rye-bread, under the title of black-bread, is largely consumed by the peasantry of Sweden, Germany, Russia, and other northern countries, and has proved itself a very nutritive and strength-producing article of diet.

Rice—the *Oryza sativa* of botanists—is a plant of Asiatic origin, but is now extensively cultivated not only in China, India, and other eastern countries, but in the West Indies and the southern states of America, as well as in the rich alluvial lands of Lombardy and in the province of Valencia in Spain. 'It is the grand material of food,' says Marsden, 'on which a hundred millions of the inhabitants of the earth subsist; and, although chiefly confined by nature to the regions included between and bordering on the tropics, its cultivation is probably more extensive than that of wheat, which the Europeans are wont to consider as the universal staff of life.' Requiring a warm climate, it cannot be grown in Britain; but we import it largely—the Carolina and Patna rice being the most esteemed in the market. It is brought chiefly in the shelled or cleaned state; though attempts have been made to import the *paddy*—that is, rice in the husk—with a view to obtaining the grains in a fresher condition.

Rice consists chiefly of farina or starch, 100 pounds from Carolina yielding, according to Braconnot, not less than 85 starch, 5 fibrous matter, 4 glutinous matter, and 5 water, the remainder being sugar, gum, and phosphate of lime. It is therefore evidently much less nutritious than any of the preceding cereals, though it is light and wholesome, and altogether a valuable food when taken along with milk or some corrective condiment. It is prepared as an article of food in various ways, either whole or ground. It may be used like barley in broth, boiled and eaten with milk, boiled and dried as a substitute for potatoes, as an accompaniment to curried dishes, or baked in puddings, which is perhaps the best mode of using it. What are called *rice-cakes* consist of about one-third of their weight of ground-rice, the rest being flour, eggs, and sugar. *Rice-water*, employed like barley-water as a demulcent, or soothing application, is obtained by boiling well-washed rice in water. Though, on the whole, light and digestible, rice possesses a constipating quality, which somewhat detracts from its value as an article of habitual use.

Maize or *Indian Corn* is the produce of the *Zea mays* of Linnæus—a cereal found native in America, but now largely cultivated, not only in the New World, but in several of the warmer regions of the Old. As an article of human subsistence, it is extensively used in the countries where it is grown; but did not, till the recent failures of the potato-crop, meet with much attention in Britain. In America, the tender young ears, in their milky state, are roasted and eaten with butter and salt as a delicacy, or boiled with meat. When green, they are also pickled as gherkins (young cucumbers); and dried, they keep all the year. When the grains are ripe, the skin is taken off, and the farinaceous part is boiled whole, or ground into meal, and made into cakes, puddings, &c. It is this meal which is chiefly known in Britain, and of which a variety of puddings, cakes, and loaves have been recommended.

Being extremely productive, maize can in general be cheaply procured; hence its importance in years when the staple of our own country fails. We find that those who live chiefly upon maize are robust, healthy, and fond of it as an article of diet. It is somewhat laxative, and requires to be taken with caution till the system becomes habituated to its use. To make good palatable *maize-bread*, Dr R. Thomson recommends the grains to be reduced to a fine meal, and then mixed with one-third its weight of best flour, and fermented. When thus prepared, the bread is dark coloured, and cannot be made much lighter than coarse wheaten bread. The shade, however, is of a peculiar yellow, not to be mistaken for that of wheat, besides that the taste is altogether different.

Peas and *Beans*, which belong to the leguminous order of plants, are consumed partly in a green state, and partly when ripe and dried. It is the latter state with which we have at present to do; and it may be stated generally, that their meal or farina is now but little used as an article of human food. Peas, split or whole, are used in the preparation of pea-soup; the meal, either pure or mixed, is still employed in some districts in the making of cakes; and, very finely ground and bolted, it is used as a supper-diet, under the name of *Glasgow brose-meal*. With regard to the amount of nitrogenous or nutritive matter which pulse and lentils

contain, it is beyond what is found in any of the cereals. The nutritive effect, however, does not agree with this theoretical conclusion, partly from their deficiency in other wholesome constituents, and partly from the difficulty with which they are digested, and the flatulence and costiveness they occasion, as well as from the acridity they are said to communicate to the blood.

Sago—Tapioca—Arrow-root.—Of a considerable number of foreign starchy products, these are the most extensively used, and best known in Britain. The first is the produce of the sago-palm (*Sagus rumphii*), a native of the East Indies and Indian Archipelago. 'The part which affords the sago is the pith; and to procure this, the body of the tree, when it is full grown, is sawn into pieces, and the raw sago cut out and put into a trough with water, in which it is well stirred, to separate the flour from the woody fibre. This is now suffered to rest, and the flour subsides to the bottom. The water is then poured off, and the meal laid upon wicker-frames to dry. To form it into the round grains in which it is imported, the sago, when moist, is passed through a cullender, and rubbed into little balls, like shot, and then thoroughly dried. The sago-tree requires to be seven years old before being fit for felling; and a full-grown specimen will yield about 600 pounds of sago. The best sago is of a slightly pinkish hue, and readily dissolves to a jelly in hot water. Several other trees besides that above mentioned yield sago, but neither so abundantly nor of so excellent a quality.' The sago of commerce is imported either as sago-meal, pearl-sago, or common brown sago, which states have reference more to its form than composition. In all, the main constituent is starch, which, being light and easily digestible, renders sago an eligible substance for the dyspeptic and invalid. *Sago-puddings* (made like tapioca) are by no means uncommon; but the common mode of use is *sago-milk*. This is prepared by soaking the sago in cold water for an hour, pouring off this water, and then either boiling slowly in milk, or in a little water to which milk is afterwards added. This mixture may be taken plain, or sweetened and seasoned to taste.

Tapioca is obtained from the tuberous root of the *Janipha manihot* by grating and washing. It is usually met with in small irregular lumps, a form it has acquired by being dried on hot plates. The heat breaks the starch globules, and renders them partially soluble in cold water. In boiling water, tapioca becomes a transparent and viscous jelly. 'In its nutritive qualities,' says Pereira, 'it agrees with sago, than which it is much purer, being free from colouring matter. It also yields a more consistent jelly than some other kinds of starch. It is principally employed as an agreeable light nourishment for invalids, as well as for children.' Tapioca-milk is made in the same way as sago-milk; but tapioca being more soluble than sago, requires only half the time for its preparation.

The pure white starchy powder known as arrow-root, is obtained from the tubers of the West Indian plant, *Maranta arundinacea*. It makes a tolerably strong jelly, stronger than that of wheat-starch, and is free from colouring matter, and also from any unpleasant taste or odour. It is used either in the preparation of puddings, gruel, or milk, like sago and tapioca. 'The best arrow-root we have,' says Webster, 'is from Antigua, Jamaica, and Bermuda; but a great deal of what is sold in London is adulterated with potato-starch, which, though a substance not very different, has not precisely the same properties. Arrow-root, like every kind of starch, boils to a jelly; but it differs from potato-starch in this respect, that the jelly formed from arrow-root will remain firm for three or four days without turning thin or sour, whereas the jelly from potato-flour, in the course of ten or twelve hours, becomes thin as milk and acescent; hence it is not so well calculated for food, and particularly infants'.' The proper value of all these substances, however, is now much better known; they contain but a small portion of gluten in proportion to the starch; and as starch can only supply heat-forming matter, they are less fitted for the purposes of nutrition. As food for the young, they are by far too largely employed; and the best American wheat-flour, good Scotch oatmeal, and barley-meal, may all be employed with advantage at different times, by way of variety, and repeated according to their agreement with the child's organs of digestion. The digestion of all these forms of food containing starch is greatly promoted by long boiling either with water or milk, as this process is just so much saved to the intestinal organs. It is thus obvious that we have a great variety of food fitted for children, of which we know the composition, and that we should prefer it to any species of compounded stuff of the constitution of which we are ignorant.

The Potato (*Solanum tuberosum*) is one of our most abundant amylaceous or starchy vegetables, and next to the cereals, is one of the most common articles of human food. Originally discovered in South America, it is now introduced into almost every quarter of the globe, where it seems to thrive, and to break into innumerable varieties, differing in shape, size, colour, flavour, and quality. Without noticing minutely the peculiarities of the numerous varieties, we may remark that those of middling size, and which become white, mealy, and void of any especial flavour when boiled, are in general the most esteemed, as they are the most wholesome and nutritious. As they are an easily raised crop, producing twice as much bulk of food from the same extent of land as wheat, potatoes are very largely grown in the British Islands, and, notwithstanding the recent failures, are likely still to be so. The disease to which we allude having drawn much attention both to their natural history and economical importance, there is perhaps no object of culture or article of diet which has elicited so many and contradictory opinions. Some would apparently have the potato altogether eradicated from our soil; others, taking a more modified view, would 'never allow it under any circumstances to occupy, as the staple aliment of any class of our population, the place of the grain-bearing plants;' while a third party see in it 'a cheap and available source of subsistence to the poor, which has had, in addition, much effect in lessening the prevalence of scorbutic, calculous, and arthritic disorders.' Without pronouncing dogmatically on the subject, we shall merely present the leading dietetic properties of the potato, as set down by Liebig, Pereira, and Webster. The most correct opinion respecting the nutritive properties of potatoes will be obtained from the consideration of their constituent principles. They have been analysed by various chemists. The analysis of Einhof, which is generally considered the best, is in 100 parts:

Water,	72·6
Starch,	15
Fibrous Matter,	7
Albumen,	1·4
Mucilage,	4
	100·

Like all the *Solanaceæ*, or Nightshade family, the potato contains a poisonous principle (solanine); but this is wholly destroyed by cooking. Citric and tartaric acids are also said to be present in various parts of the growing plant, and to these are likely to be ascribed the reputed antiscorbutic properties of the tuber. The fibrous matter in Einhof's analysis appears to be a peculiar modification of starch, which, as well as that substance, may be employed for food; but it is to be noticed that there is no gluten, unless the albumen be considered as nearly the same thing. According to Johnston's *Chemistry of Common Life*, the potato contains 75 per cent. of water, and 25 of dry food. Of 100 parts of this dry food, again, 92 parts are starch and 8 parts are gluten, or a corresponding principle. Potato-meal is thus remarkably similar to rice-meal. No doubt can

be entertained of the wholesome nature of the potato, when we consider the numerous hardy peasantry of Ireland, many of whom subsist almost entirely upon this useful vegetable. It must not, however, be imagined that potatoes contain the same nutritive powers as bread, weight for weight. It has been estimated, as the result of experiments made by Percy and Vauquelin, that one pound of good bread is equal to two and a half or three pounds of potatoes, and that seventy-five pounds of bread and thirty of meat are equal to three hundred pounds of potatoes.

In Britain, potatoes are generally brought to table boiled plain; but in France they are cooked in a great variety of ways, and furnish very agreeable dishes. *Potato-soup* (see PREPARATION OF FOOD) is a very palatable and thrifty mode of cooking; and *mashing* them with various ingredients, though it produces a more savoury dish, does not certainly contribute to their digestibility. It is of little signification, as affecting the digestibility, whether the potato be roasted, or baked, or boiled, provided the quality and the cookery be unimpeachable. The new or immature potato is much less easily digested than the fully ripened tuber, and should certainly be forbidden to the majority of dyspeptics. Early and forced potatoes must be less easily digested than those which have been grown with the advantages of free exposure to the air and the sunshine. As already stated, potatoes are used in the manufacture of loaf-bread; and *potato-starch*, which is nothing more than dry starch-powder, is used not only in fine bread and pastry, but as a substitute and adulterant of arrow-root. *Bright's nutritious farina* is said to be a carefully prepared potato-starch, slightly scented; and we believe several of the 'farinaceous foods' of the shops are of similar origin. The most that can be said of them is, that they are sufficiently light, and not unwholesome, but by no means nutritious.

The *Cabbage tribe* (*Brassica*)—which includes the common white and red cabbages, the savoy, greens, cauliflower, broccoli, &c.—is pretty extensively cultivated in Britain (see KITCHEN-GARDEN) for the purposes of human food. The parts used are the leaves which *heart* or gather together; and in the case of the cauliflower and broccoli, it is the young and compact flowering heads. As nutritive products, they rank high theoretically; but as they contain upwards of 90 per cent. water, a larger quantity requires to be consumed for the purposes of nutrition than would be either wholesome or agreeable. For healthy constitutions, they supply a valuable mixture with animal food; but for the dyspeptic, they are apt to prove indigestible, and productive of flatulency.

The Turnip (*Brassica rapa*), which belongs to the same family, is perhaps still more largely consumed. The varieties best adapted for human food are the Swedish, yellow, and Dutch, all of which contain a considerable quantity of sugar and mucilage, with but little gluten. A hundred parts of turnip-bulb yielded Boussingault 92·5 water, and 7·5 solid matter; and this, when dried, only 1·7 of nitrogen—being but a third of the amount found in dried cabbage. Sir Humphry Davy estimates the nutritious matter of turnips at about 4 per cent.; but though thus slightly nutritive, they form an excellent culinary vegetable, and are either eaten alone, mashed, or cooked in soups or stews. Pereira regards them as of easy digestion, and has never seen them produce flatulence when well boiled. Turnip-tops, or the young leaves gathered in spring, are occasionally used in England as greens, but are very apt to disorder the bowels.

The Carrot and *Parsnip* are two well-known umbelliferous roots, possessing highly nutritive properties, if chemical composition is to be taken as the test of alimentary value. They contain vegetable fibrin, albumen, sugar, and a volatile oil; 1000 parts yielding 95 sugar and 3 starch, or about six times the amount of sugar found in potatoes. They are valuable culinary vegetables in soups and stews, and ought to be much more largely used. The fibrous matter they contain renders them somewhat difficult of digestion if not well boiled—a matter admitting of very easy remedy.

Beet-root, though largely made use of on the continent, is chiefly employed in England as a garnish for salads and other dishes, and as pickle. According to the experiments of M. Achard, 14 pounds of beet yield 1 pound of sugar; hence the manufacture of sugar from this root, and also its value in a culinary point of view. During the recent potato-failures, various preparations of beet were recommended as food for the poor; and among others, *beet-bread* from an admixture of finely rasped beet and wheaten flour, fermented and baked in the usual form. 'We have had the experiment tried,' says Dr Lindley, 'by rasping down a red beet-root, and mixing with it an equal quantity of flour; and we find that the dough rises well, and forms a loaf very similar to good brown bread in taste and appearance. We regard this as an important discovery, because no crop is so readily cultivated, or will yield so large a return as beet, and likewise because of its great value in point of nutrition.' We may add, that either the red beet, the white sugar-beet, or the carrot, may be used with success in this manner.

Of the vast variety of garden vegetables used as salads, pickles, garnishes, and so forth, none are consumed in such abundance as to entitle them to especial notice. Many of them are no doubt useful, others are useless, and not a few positively hurtful, though fashion and caprice may give them a place on our tables. Some notice of the more prominent—as lettuce, radish, spinach, celery, asparagus, artichoke, parsley, cress, onion, and the like—will be found under KITCHEN-GARDEN and COOKERY.

Sugar.—As already mentioned, sugar exists both in vegetable and animal substances, but more abundantly in the former. In many of the products already noticed, the saccharine principle forms no unimportant item, though not in such proportion as to be considered characteristic. We now come to consider it as a distinct principle, and as an article of vast dietetic importance. Sugar, as a vegetable product, is found in considerable quantity in such dried fruits as the currant, raisin, fig, date, tamarind, and so forth; and these are now pretty largely consumed in Britain. Thus, figs yield about 60 per cent. of sugar; tamarinds, 12; prunes, 16; and dates, 35; and there can be no doubt that these, as well as many of our ripe fleshy fruits, owe their chief alimentary value to its presence. It is, however, as a separate and prepared article that we have now to do with it—as a substance obtained by art from the sugar-cane, the maple, the beet, the palm, and other plants yielding it in abundance. Though procured from the maple in America, from the beet on the continent, and from the palm in the East Indies, it is solely from the sugar-cane of the tropics that Britain obtains her supply, amounting annually to nearly 7,000,000 hundredweights. When the canes, of which there are several varieties, have attained a certain height and age—about twelve or thirteen months—the cuticle having become smooth, dry, and brittle, they are cut, stripped of their leaves, and crushed between rollers to express the juice, which is mixed with lime to neutralise the free acid present, and render more liquid and separable the uncrystallisable portion, known as molasses or treacle. The juice is now heated to the temperature of 140°, and separated from the scum, and again heated several times, and at length allowed to drain, for the separation of the *molasses* and the crystallisation of the sugar. The *raw* or *brown sugar* thus formed is again purified, by being acted upon by lime and bullock's blood: the one serving to neutralise the acidity of the liquids; the other, by the coagulation of the albumen, effecting the clarification and mechanical separation of any foreign insoluble matters. Reduced

to a certain sirupy consistence, the sugar is poured into moulds, and agitated for a certain time, to prevent the formation of large crystals, and secure a compact mass of closely adherent, small, and glistening grains. This constitutes *loaf-sugar*, the quality of which depends greatly on the lowness of the temperature at which the boiling has been effected. When sugar thus refined has been again dissolved, and left to crystallise slowly at a somewhat elevated temperature, in boxes crossed with threads, to form centres of crystallisation, *sugar-candy* is formed; or if sugar so dissolved is made to cool more quickly, a transparent solid is obtained, known as *barley-sugar*. Sugar in one or other of these states constitutes the basis of almost all *confectionary*, as acidulated drops (sugar and tartaric acid), toffy, hardbake, comfits, lozenges, and the like. It forms also an excellent antiseptic, and for this purpose is used as a *sirup* for preserving fruits, roots, &c., as well as for the curing of meat and fishes.

In whatever form sugar or the saccharine principle may be made to appear in commerce or in diet, its ultimate composition, when pure, is carbon, oxygen, and hydrogen; or more simply, carbon and the elements of water. It contains no azotised principle, and thus its function in the animal economy is to supply heat and not nutrition. 'The fondness of children for saccharine substances'—we quote Pereira—'may be regarded as a natural instinct; since nature, by placing it in milk (woman's milk contains upwards of 6 per cent. sugar), evidently intended it to form part of their nourishment during the first period of their existence. Instead, therefore, of repressing this appetite for sugar, it ought rather to be gratified in moderation. The popular notion of its having a tendency to injure the teeth is totally unfounded; Dr Wright informs us that no people on the earth have finer teeth than the negroes of Jamaica. Sugar is readily digested by the healthy stomach; though in some dyspeptic individuals it is apt to give rise to flatulency and preternatural acidity of the stomach. In some diseases—as diabetes, for example—it should be altogether excluded from the diet.' Contrary to this opinion as to the digestibility of sugar, Dr Robertson pronounces pure sugar to be 'by no means easily digested,' and that it only becomes so when sufficiently mixed and diluted with other juices. Molasses, on the other hand, from containing more component water, is more easily digested, at the same time that it is usually laxative in its effects. It is still, nevertheless, saccharine matter, and is still apt to irritate the digestive organs, and thus to interfere with and derange the processes of ultimate assimilation.

Honey, though, strictly speaking, obtained through the medium of the animal kingdom, may with little impropriety be considered in this place. It is but a weaker form of sugar, and although elaborated by the bee, is still found ready-made, if we may so speak, in the flowering apparatus of many plants. It consists chiefly of grape-sugar, containing a greater or less amount of cane-sugar. Besides these two sugars, honey also contains a free acid matter not yet well understood, mucilage, sometimes a little wax, together with colouring and aromatic matter. These adjuncts differ, according to the kind of flowers on which the bees feed; and occasionally honey has been known to possess narcotic and poisonous properties. Its dietetic properties are thus spoken of:—Like treacle, honey often acts as a laxative, and to a greater degree. But, like all other concentrated forms of saccharine matter, the digestibility of honey is only a comparative question; and, although honey may be much less apt to derange the functions of assimilation than cane-sugar or treacle, it is nevertheless by no means easily digested when the stomach is either weakened or otherwise less equal to its duties; and should always be used cautiously by the dyspeptic, if used at all by them. With some constitutions, it by no means agrees, and has to be carefully avoided.

The fleshy fruits, as the apple, pear, plum, peach, and the like, though generally consumed during their seasons, cannot be regarded as a staple of food, though they are all more or less nutritious. About 80 parts in 100 are water, the rest consists of sugar and peculiar acids, associated with more or less gluten. According to Johnston, the perfectly dry gooseberry is about as nutritive as ordinary wheaten flour. Some, as the pear and apple, are employed in the manufacture of BEVERAGES; and as to their acid properties, these will be considered under the principles of MEDICINE.

ANIMAL FOOD.

Animal, like vegetable substances, are resolvable into ultimate and proximate principles. The *ultimate elements* of 100 parts ox-blood, for example, are—51·95 carbon, 7·17 hydrogen, 21·39 oxygen, 15·07 nitrogen, and 4·42 insoluble mineral matter. Again, 100 parts beef yield 52·59 carbon, 7·89 hydrogen, 19· oxygen, 15·22 nitrogen, and 3·30 insoluble ingredients. Comparing this with what has been said of vegetables, the vast preponderance of nitrogenous or nutritive matter will be readily perceived. The *proximate principles* of animal food are—fibrin, or the fleshy fibre of meat when boiled to rags; gelatine, or animal jelly; albumen, or white of eggs; oil and fat; osmazome, which gives to meat its peculiar flavour; kreatine, a peculiar crystallisable juice; caseine, such as the curd of milk or cheese, which is nearly allied to albumen; and, we may add, sugar, as in the case of milk. Of these principles are all animal bodies composed; always bearing in mind the large percentage of water which they contain. These principles vary considerably in ultimate composition—thus, 100 parts of fibrin yield 53·36 carbon, 7·03 hydrogen, 19·68 oxygen, and 19·93 nitrogen; while albumen yields 50·00 carbon, 7·78 hydrogen, 26·67 oxygen, and only 15·55 nitrogen. Of course their relative values in point of nutrition depend upon the ultimate constitution; and this must be obtained with accuracy before any comparison can be instituted between fibrin and gelatine, gelatine and albumen, or albumen and caseine.

In treating of animal food, some writers attempt to classify it according as it may be derived from the flesh, blood, viscera, bones, cartilages, ligaments, cellular tissue, milk, &c. As our limits, however, prevent any such minute consideration, we shall merely remark, that all these portions of the animal body are less or more prized and made use of; and that they differ in nutritiousness, not only according to the kind or species of the animal, but according to the age, sex, food, and mode of life of the individual. Thus the flesh of young animals is more tender than that of old; that of the entire male adult, coarser and tougher than that of the female. Again, feeding and exercise are not without their influence; and just as the fibres of flesh are loose, tender, and minute, so are they the more easy of digestion. With these preliminary remarks, we shall proceed to notice in detail the leading articles of animal food made use of in Britain.

Beef, or the flesh of the full-grown ox, is largely consumed in Britain, perhaps more largely than a due regard to health and economy would allow. The quality of this article depends upon a variety of circumstances, such as the breed, sex, and age of the animal, and likewise the kind of food with which it has been supplied. 'Bull-beef,' says a leading authority on *cuisine*, 'has a strong disagreeable flavour, and is dry, tough, and difficult of solution. The flesh of the *ox* is more soluble; the fat is better mixed, the meat more sapid, and highly nourishing and digestible, if the animal is not too old. The flesh of the *cow* is sufficiently fit for nourishment, but is inferior to ox-beef; *heifer*-beef, or that of the young cow, is much esteemed; but that of an old fatted cow is bad. The beef of the larger varieties of the ox is inferior to that of the smaller breeds; the

former is in perfection from five to seven years old; the latter may be taken a year or two sooner. Grass-fed beef, or that produced from good farm-produce, is always better flavoured and more digestible than that reared from oil-cake, brewers' wash, and the like.' Beef is consumed both in a fresh and salted state; it is also pickled, smoked, and otherwise prepared. Salted, it is more difficult of digestion, while the salt, moreover, destroys a considerable portion of its albumen. Preserving it fresh in hermetically sealed vessels, from which the air has been expelled, is now extensively adopted, with the best results. For various modes of pickling and preserving, as well as for an estimate of the comparative merits of boiling, broiling, and roasting, the reader is referred to the following article on the PREPARATION OF FOOD.

Veal, or the flesh of the calf, is tender and nourishing, but not so easy of digestion as the prime parts of beef and mutton. Veal, particularly if it be young, contains much gelatine, as is the case with all young animals, and therefore yields a great deal of soluble matter when boiled long in water. This fact has led to the idea of its being more nourishing than meat which is less soluble; but this does not follow, for the gastric juice acts differently from water, and can digest what that fluid cannot. Veal contains more nitrogenised matter than beef.

Besides beef and veal, strictly so called, the intestines, heart, lungs, bones, marrow, cartilage, &c., of the ox are variously made use of; none of them, however, possessing the same amount of nutritious matter as the true flesh, nor being so digestible and wholesome. 'Animal flesh being identical with our own flesh and blood, say chemists, it requires neither addition nor subtraction to render it nourishing;' but in order that it may reach the different organs, it is necessary that it should be reduced to a liquid form (blood).

Mutton, or the flesh of the full-grown sheep, is also extensively consumed in Britain, and that almost wholly in a fresh state. Compared with beef, it is lighter, and more easily digested, owing very probably to the greater fineness of the fibres. 'The quality of mutton,' says the authority already quoted, 'varies much in the different breeds. In the large long-haired sheep, it is coarse-grained, but disposed to be fat. In the smaller and short-woolled breed, the flesh is closest grained and highest flavoured; but the quality is probably most affected by the food on which the flocks are fed. Those which range over the mountainous districts of Wales and Scotland, or the chalk-downs of England, and feed upon the wild herbage, possess a flavour very superior to those kept on rich pastures and marsh-land. Marsh-fed mutton often becomes extremely fat, but the meat has a rank taste. Turnips, hay, chaff, bran, corn, and other vegetables, as likewise oil-cake and grains, are employed for fattening sheep; but such mutton is never so good as that produced where the animals range at freedom. *Tup*-mutton, or the flesh of the ram, has a strong disagreeable flavour, and is usually tough; ewe-mutton, if under two years old, is good, but after that, it becomes hard and tough; wedder-mutton is the most esteemed. Mutton is in perfection at five years old, being then sapid, full-flavoured, and firm, without being tough; and the fat has become hard. Mutton under three years old is deficient in flavour, and is of a pale colour. *Lamb*, as the flesh of the young sheep is termed, is more tender and less exciting than mutton, but is not readily digested. It receives the name of lamb from the time it comes into season, in April or May, till the ensuing Christmas.

Pork, or the flesh of the pig, is invariably set down by writers on dietetics as difficult of digestion, but less so when pickled and cured than when fresh. Those who pursue the occupation of curing, cut the carcass in pieces, and pack it in kits formed to hold from one to two hundred pounds' weight. A brine is then made by dissolving salt in water, until the mixture is so thick that an egg will swim in it. This is boiled, and poured upon the pork after it has cooled. Russian pork, always much esteemed, is steeped in a brine containing 2 pounds of loaf-sugar and 3 ounces of saltpetre, to 6 pounds of salt, the whole being boiled in 6 gallons of water. After brine is added to pork in kits, the end of the receptacle is fixed in, and the article is usually sufficiently cured in a few days.

Hams are the cured hind-legs of the pig, and are considered the finest parts of the animal. They are generally in great request, and form an article of extensive consumption in Britain. The following are general directions for curing them: In the first place, the legs require to be cut in a neat rounded form, and it is usual to prepare a number at a time. Being properly prepared, pack them with rock-salt in a suitable tub or cask, being careful not to lay the flat sides of the large pieces upon each other, and filling the intervals with hocks, jowls, &c. To every 300 pounds of meat, take 20 pounds of rock-salt, or Onondago coarse salt, 1 pound of saltpetre, and 14 pounds of brown sugar, or half a gallon of good molasses, and as much water (pure spring-water is the best) as will cover the meat; put the whole in a clean vessel; boil and scum; then set it aside to cool, and pour it on the meat till the whole is covered some three or four inches. Hams weighing from 12 to 15 pounds must lie in the pickle about five weeks; from 15 to 25 pounds, six weeks; from 25 to 45 pounds, seven weeks. On taking them out, soak them in cold water two or three hours, to remove the surface-salt; then wipe and dry them. It is a good plan, in cutting up, to take off feet and hocks with a saw instead of an axe, as it leaves a smooth surface, and no fractures for the lodgment of the fly. Some make only six pieces of a trimmed hog for salting, but it is more convenient, when intended for domestic use, to have the side-pork, as it is called, cut in small pieces. The goodness of hams and shoulders, and their preservation, depend greatly on their smoking, as well as salting. The requisites of a smoke-house are, that it should be perfectly dry; not warmed by the fire that makes the smoke; so far from the fire, that any vapour thrown off in the smoke may be condensed before reaching the meat; so close as to exclude all flies, mice, &c., and yet capable of ventilation.

Bacon is the whole side of a pig cured. The method of preparation is as follows: After being killed, the carcass should not be scalded to remove the bristles, as in the case of pork, but singed off by being covered lightly with straw, to which fire is applied. When the burning straw has cleared one side, the other side may be cleared in the like manner. By this means all the hair is to be singed clean off, but without scorching the flesh, and then the skin is to be well scraped as a finish. This singeing process gives a fine firmness to the bacon, which scalded bacon never possesses.

Bacon has been much vaunted by some as a remedy for indigestion, while by others a totally different opinion is entertained. 'In the large majority of cases,' says Dr Robertson, 'it cannot be so; but, on the contrary, must tax still further the powers of the stomach, or irritate still further its tissues, which under such circumstances may be already in a state of morbid sensitiveness. Bacon is obtained from the most difficultly digested of the meats, the fleshy fibres of which are toughened by the salt and by the drying. That fat is rendered more digestible by being impregnated with salt, is an admitted fact; and this must of course qualify these strictures on the use of bacon. But the lean of bacon is rendered more difficult of digestion by the same process that has increased the digestibility of the fat; and the fat is not by any means so altered in character, as no longer to irritate the debilitated stomach. I have no hesitation in saying, that

in the greater number of cases of dyspepsia, bacon does harm.'

Brawn.—Boars are also fattened for the purpose of procuring an article of food under this name. Male pigs of all ages are put into feeding with this view, but those experienced in such matters prefer them of the age of two years. They are kept separately, in pens which will not permit of their turning round, perfect inactivity being held to conduce to their fattening. Their food is beans, with water, into which a small quantity of sulphur has been put. The collar of the animal is the part prepared for brawn, by the processes of pickling and drying. A large collar will weigh about thirty pounds, and is valued at about £3 in the market.

Lard is that part of the fat of the pig which melts easily, and forms a fine, soft, white grease. It is extensively used not only in household economy, but by the pastry-cook, apothecary, and perfumer. It should be, according to Martin Doyle, of *two* qualities: the finest and whitest—that taken from the sides—should be chopped into small pieces in a pan, over a slow fire, and kept constantly stirred, lest it should stick to the sides of the boiler; then strained, and put into bladders. The bladders should be turned inside out, and thoroughly purified by having all the fat cut out, and be well blown and dried in the open air. Lard of the first quality, when well made, is far better than any salt butter for cookery, and, from the delicacy of its colour, is used by confectioners for the finest kinds of cake and pastry. The inferior lard is obtained from the intestines, and is treated as the finer lard in every particular. The *blood* of the pig, we may also observe, furnishes a distinct article of food—being used in the preparation of the black-puddings of the shops.

Venison—Hare—Rabbit.—The flesh of the deer, hare, rabbit, and other game found in the British Islands, can never be considered as an article of general consumption. The comparative scarcity of these animals, and the fact that they are in season or fit for food only during the colder months of the year, when they become objects of fashionable capture, render them rather luxuries for the middle and higher classes, than a staple of food for the bulk of the population. The ultimate analysis of their flesh is much the same as that of the domestic animals, differing, however, in proximate character, and also in containing certain flavouring principles of a bitter or acid nature. From their constant motion and exercise, wild animals acquire a drier and harder flesh than that of the tame; and those parts which have the least motion—as the back of a hare, for example—are most juicy and palatable. From the same cause, the fluids of these animals are more heating, and much more apt to putrefy than the fluids of the domestic kinds.

The term *venison*, though applicable to the flesh of all animals which are caught by way of hunting, is generally restricted to that of the deer kind—as the buck, the doe, the hart, and the hind. When well fed, killed at the right season, and properly dressed, venison forms a palatable as well as a wholesome and readily digested food. To the injury of health, however, it is generally eaten when half-putrefied, notwithstanding its natural tendency to putrescence. Cooked in this state, it forms highly objectionable food for those predisposed to scurvy or putrid diseases, and should never be partaken of unless with the addition of vinegar, acid of lemons, or some other corrective. The flesh of *hares* was in high repute among the ancients, both in dietary and in medicine. The youngest and fattest are the best; and those bred on plains and mountains are preferable to those that live in moist places—the former feeding on aromatic herbs, which gives to their flesh a peculiar flavour. *Rabbits* are in more common use than hares; and in certain districts of the country no man who has tenpence or a shilling to spare need be in want of a pair to furnish himself and family with a nice Sunday dinner. Rabbits are either found wild in warrens, or are reared in sheds and hutches, as directed in No. 41. The former furnish the most dainty and agreeable food—having a greater opportunity of feeding on sweet aromatic herbs—such as thyme, juniper, and the like, which imparts to their flesh a rich and more pleasant flavour. Though a rabbit is in many respects similar to a hare, yet the flesh of the former is more tender, as well as more juicy, than that of the latter, and after boiling, becomes pale, and may be termed *white meat*. On the whole, it affords a good and nourishing diet, if taken at a middling age and size: when too young, it is not esteemed wholesome; and when old, it becomes dry, hard, and difficult of digestion. Rabbits are in prime season from the middle of October till the end of January.

Poultry—Game-birds.—So far as experience goes, the flesh of all birds is edible, though that of some tribes is less palatable and wholesome than that of others. As an article of food, it is pretty largely consumed in this country—the domestic fowl, turkey, goose, duck, pigeon, partridge, grouse, and pheasant, being the species which afford the chief supply. According to Brande, 100 parts of chicken-flesh yield 73 water, 20 albumen or fibrin, and 7 gelatine—that is, a total of 27 per cent. nutritive matter. Schlossberger's estimate is somewhat less; but of course chemical analysis will differ according to the condition, age, and other particulars of the specimen examined. The pectoral muscles which move the wings are drier and more tender than those which move the legs. The tendons of the legs are also very strong, and at a certain age become bony; but the flesh of the legs, when sufficiently tender, either from the bird being young, or from long keeping, or sufficient cookery, is more juicy and savoury than that of the wings. Of a few birds, especially the woodcock and snipe, the legs are at all times preferred to the breast. In the black-cock, the outer layer of the pectoral muscle is of a dark-brown colour, while the inner is white. A similar difference is observed in many other birds, and perhaps it is general in a slight degree. The muscular organs of birds differ from those of quadrupeds in their flesh never being marbled, or having fat mixed with the muscular fibres.' This is so far advantageous, as the fat of most birds, the aquatic in particular, is extremely difficult of digestion and assimilation.

It is usual for writers on dietetics to classify the flesh of feathered animals according to its colour, or according to the leading habits of the birds as regards their food and mode of life. Adopting some such distinction, Dr Pereira makes the following generalisations: 'The meat of the common fowl, turkey, and the like, is *white-coloured*, contains but little osmazome, when good, is generally liked, and when young, is exceedingly tender. Chicken flesh is nutritious, and when young, is perhaps the least stimulating of animal foods. It is often retained on the stomach of invalids when other meats would be immediately rejected. Chicken-broth is well adapted for irritable stomachs. The flesh of the wild gallinaceous birds, as the grouse, blackcock, &c., is *darker coloured*, firmer, richer in osmazome, somewhat less digestible, and more stimulating than that of the chicken. When sufficiently kept, it acquires a peculiar odour, called *fumet*, and an aromatic bitter taste, most sensible in the back. In this condition, it is said to be *ripe* or *high*, and is much esteemed by epicures as a luxury. The flesh of aquatic fowl, as the goose and the duck, is mostly firm, penetrated with fat—which often acquires a rancid and fishy taste—and is more difficult of digestion. It forms, therefore, a less appropriate aliment for invalids.' On the whole, it may be remarked that the younger and smaller the bird, the

more delicate and tender the flesh; but the female is generally more tender and delicate than the male; that domestication renders birds more fleshy and tender; and that the more cleanly and carefully the animals are reared, the more wholesome and palatable their flesh becomes. It may be also added, as the result both of experience and experiment, that poultry is more easily digested when broiled; is somewhat less digestible when roasted; and is least easily digested when boiled. The less it is mixed and qualified by sauces, stuffings, &c., the better.

The eggs of birds—the hen, duck, goose, and turkey—are largely consumed in Britain, partly as a direct article of diet, and partly in puddings, pastry, and fancy-breads. It is scarcely necessary to observe that the egg of the common fowl is that most extensively used, both on account of its superior flavour and digestibility. Both the white and yolk consist chiefly of albumen, the former almost entirely so. Thus, 100 parts of white of egg yield about 80 water, 16 albumen, and 4 incoagulable mucilaginous matter; the yolk about 54 parts water, 18 albumen, and 28 a peculiar yellow oil. The white, upon an average, is about twice the weight of the yolk; and deducting from the weight of the whole egg one-tenth for the weight of the shell, and the half of the remaining nine-tenths for water, and less than a fourth of the further remainder for the oily portion of the yolk, about a third of the entire egg appears to consist of azotised or nutritious matter.

With respect to the eligibility of eggs as an article of diet, much depends upon the mode of preparation. 'If lightly boiled,' says Dr Robertson, 'the digestion of the yolk of egg is hardly ever felt. Not so the white: when boiled, this almost always irritates the disordered stomach, and by the dyspeptic and invalid, it should not be eaten. The same observations apply to some extent to eggs when made to form part of a pudding: the yolk is still the part which is most easily digested—the white that which is the more likely to disagree; but the latter is not so likely to prove injurious as when eaten alone, and unmixed with other things. The probable reason of this is the same as that assigned for the increased digestibility of milk when mixed with flour or oatmeal; the albumen being prevented from coagulating into large masses, is offered to the action of the gastric secretions in smaller portions, which are therefore more readily acted upon by it. It is an important fact, that either the white or the yolk of egg, if eaten raw, and therefore uncoagulated, is much more easily digested than when it has been previously boiled. The albumen is of course, in this case, coagulated by the acid secretion of the stomach, as the first step to its digestion; but this coagulation is different from the coagulation by heat, and does not offer the same degree of resistance to the solvent powers of the stomach. A raw egg is not, then, liable to the objections, on account of its degree of digestibility, that a boiled egg may deserve; and, on the contrary, it would seem that there are few articles of diet which are so quickly or so easily digested as uncoagulated albumen. Lightly poached egg is probably more digestible than egg boiled in the shell; and this may be owing to the more rapid coagulation of the albumen, and the shorter time it is necessary to expose the albumen to the heat, in order to render it sufficiently cooked for palatability. It is hardly necessary to say, that fried eggs, involving the addition of fat, part of which is necessarily browned—that is, burned or converted into empyreumatic oil, and likewise involving the exposure of the albumen to a much higher temperature than that of boiling-water, must be much less easily digested than boiled eggs. The digestibility of egg is much influenced by its having been recently laid. Containing so much azotised matter, and the usual proportion of sulphur and phosphorus, egg soon undergoes the changes of decomposition; and probably to a considerable extent before these are to be detected by the sense or smell.'

Turtle.—Of the reptiles, which rank next in the descending scale of animated life, none can be regarded as a staple of food in this country. We leave the edible frog to our continental neighbours, and the turtle to the inhabitants of those regions of which it is a native. As a luxury, however, turtle is consumed by the wealthy and great, and is yearly becoming more common, as the facilities of steam-navigation bring it in much better condition, and much more abundantly. When cooked, the flesh of the green or edible turtle somewhat resembles that of chicken or veal; is pale, watery, soft, rich in gelatine, poor in fibrin, and contains little or no osmazome. It is said to be of easy digestion, and nutritive; and by decoction, yields highly restorative soups. The eggs of several of the turtle family are eaten as a palatable article of food.

Fish—Crustacea and Shell-fish.—This division embraces a large amount of the food of our countrymen, and is steadily, though slowly, on the increase. In the articles ANGLING and FISHERIES, the natural history and modes of capture of the fishes chiefly consumed in Britain are sufficiently detailed; we shall here restrict ourselves to their dietetic condition and importance. Unlike the flesh of birds, that of fish is not always to be eaten with impunity. Many, indeed, are highly poisonous; and even the best are not always in season. They are said to be in season after full recovery from the operation of spawning, up to the time when the roe and milt are ripe, and about to be shed—and the nearer this point the better. Almost every portion of the common edible fishes is available as food; but the muscular, fleshy, or flaky part is that which forms the staple. It differs little in composition in the various kinds, being composed mainly of water, albumen, and gelatine. Thus, 100 parts of cod-flesh yield 79 water, 14 albumen or fibrin, and 7 gelatine; and that of the sole, 79 water, 15 albumen, and 6 gelatine. In many fishes, this flesh is mixed or covered with fat or oil, as in the salmon, herring, pilchard, &c.; but after the spawning season this fat is greatly diminished: in others, as the cod, skate, &c., the fat seems concentrated in the liver, leaving the flesh devoid of it. Fish-flesh contains, theoretically, a fair amount of nutritive matter; but this is greatly depreciated in many instances by its indigestibility. Taken in the aggregate, Dr Robertson arranges their relative indigestibility thus: 1. White-fleshed fish; 2. Flat-fish; 3. Shell-fish; 4. Fresh-water fish; 5. Red-fleshed fish; and, lastly, the more oleaginous fish. From the quantity of water which the flesh of fish contains, it is less satisfying to the appetite than butcher-meat or poultry, at the same time that it is less substantial and nourishing. Besides the albumen, gelatine, mucus, and oil usually found in the substance of fishes, there are phosphates, chlorides and iodides of lime, magnesia, soda, &c., which may give to it peculiar dietetic and medicinal properties.

For dietetic purposes, fishes have frequently to undergo some sort of preparation, varying according to the situation, the necessities, or the tastes of the consumers. 'When circumstances permit,' says Dr Fleming, 'they are in general used in a *fresh* state; and in large cities, where the supply must be brought from a distance, various expedients are resorted to, to prevent the progress of putrefaction. By far the best contrivance for this purpose is the well-boat, in which fish may be brought to the place of sale even in a live state. Placing the fish in boxes, and packing with ice, is another method, and has been extensively employed, particularly in the supply of the metropolis with salmon. In many maritime districts where fish can be got in abundance, a species of refinement in taste, or at least a departure from the simplicity of nature, prevails, to gratify which the fish are kept for some days until they

begin to putrefy. When used in this state, they are far from disagreeable, unless to the organs of smell. Where fish are to be procured only at certain seasons of the year, various methods have been devised to preserve them during the periods of scarcity. The simplest of these processes is to *dry* them in the sun. They are then used either raw or boiled, and not unfrequently, in some of the poorer districts of the north of Europe, they are ground into powder, to be afterwards formed into bread. But by far the most successful method of preserving fish, and the one in daily use, is by means of salt. For this purpose they are packed with salt in barrels, as soon after being taken as possible. In this manner are herrings, pilchards, cod, and salmon, as well as many other kinds of esculent fish, preserved. The fish, in many instances, after having been salted in vessels constructed for the purpose, are exposed to the air on a gravelly beach, or in a house, and dried. Cod, ling, and tusk so prepared, are termed in Scotland *salt-fish*. Salmon in this state is called *kipper;* and haddocks are usually denominated by the name of the place where they have been cured. After being steeped in salt, herrings are in many places hung up in houses made for the purpose, and dried with the smoke of wood. In this state they are sent to market under the name of *red-herrings*. Although salt is generally employed in the preservation of fish, whether intended to be kept moist or to be dried, vinegar in certain cases is added. It can only, however, be employed in the preservation of those fish to which this acid is served as a sauce.' By the above processes of salting, drying, and smoking, the digestibility of fish is greatly impaired; though in some cases they may thereby be rendered more palatable and nutritious.

But though salting may thus impair the digestibility of fish, by hardening the fibres of the flesh, yet fresh fish are recommended by physicians to be eaten with a considerable quantity of salt. When salt is eaten with fresh fish, according to Dr Robertson, 'the fibres are not hardened by the salt; and the only effect of the salt is to stimulate the stomach so far as to promote or produce its speedy digestion. The more greasy the fish, the more salt should be eaten with it, and vinegar is usually a palatable and advisable addition. It answers the same end as salt, in correcting the effect of the fat, &c.; but this remark, it must be observed, applies only to such stomachs as can bear a moderate degree of acid without inconvenience. Broiling and boiling, especially the latter, are undoubtedly the best ways of cooking fish, both for wholesomeness and digestibility. Fried fish, from being cooked in butter or fat, is much less digestible. If the fish be not of a greasy character, broiling is the most digestible mode of cooking it; if greasy, the fat is rendered more or less empyreumatic, and by so much less wholesome, by broiling—and boiling is then the way of cooking it. With the exception of salt—and in the case of oily fish, of sugar—all addition to fish, in the form of sauce or condiment, of necessity renders its digestion more difficult. The melted butter with which fish is almost invariably eaten, must render it less digestible; and the dyspeptic who will eat fish, should not add to it butter in any form.

'The same observation, as to difficulty of digestion, is applicable to all the different kinds of shell-fish and crustacea. Muscles, cockles, &c., are less easily digested than oysters, and it is quite a mistaken notion that these are comparatively harmless in this respect. Prawns, shrimps, &c., like the lobster and crab, have hard, dense fibres, that are not readily dissolved by the gastric secretions. The character of the fibres, indeed, will afford a trustworthy guide—other circumstances being equal—to the digestibility of the different kinds of fish. Thus the denser fibres of the skate render this fish less digestible than the turbot; and the same circumstance makes the halibut less digestible than the salmon.' As to the nutritive properties of crustacea and shell-fish, they are in general greatly over-rated. In the oyster, for example, 100 parts of the flesh yield about 88 water, and only 12 of solid or nutritive matter; while 100 parts of butcher-meat yield, on an average, from 25 to 28.

Milk—Butter—Cheese.—These are indirect animal products, all largely consumed in every country, whether savage or civilised. Milk, which is obtained only from the class Mammalia, and intended by nature for the nourishment of their young, is the basis of the whole—furnishing, according to certain changes, which it readily undergoes, cream, butter, curd, cheese, whey, and so forth. Intended by nature as the sole food of the young mammal, it necessarily contains all the elements of respiration and nutrition. Blood, flesh, bones, and every other tissue, are formed from its elements: it is, in fact, a perfect food—that is, perfect in its kind, up to a certain stage of animal development. Its proximate constituents are caseine, butter, sugar of milk, various salts, and water; and these differ not only in various animals, as the following analyses will shew, but also according to the food, the age, and the period after parturition. Thus 100 parts of

	Caseine.	Butter.	Sugar.	Salts.	Water.
Cow's Milk yield .	4·48	3·13	4·77	0·60	87·02
Ass's " .	1·82	0·11	6·08	0·34	91·65
Woman's " . .	1·52	3·55	6·50	0·45	87·98
Goat's " .	4·02	3·32	5·28	0·58	86·80
Ewe's " . .	4·50	4·20	5·00	0·68	85·62

Such analyses, however, are to be regarded only as approximations, for the food, age, &c., must ever be taken into account. A cow fed on carrots, for example, yields a milk differing from that which she produces when fed on beet-root:

	Caseine.	Butter.	Sugar of Milk.	Salts.	Water.
Carrots, . .	4·20	3·08	5·30	0·75	86·67
Beet, . . .	3·75	2·75	5·95	0·68	86·87

Notwithstanding these differences, there is always in the milk of a healthy mother sufficient nutriment for the young; the cream and butter yielding fat, which, along with the sugar, subserves the purposes of respiration or heat; the caseine the elements of nutrition and growth; and the salts—chiefly phosphates of lime, magnesia, soda, and iron—matter for the construction of the solid skeleton. Milk as an article of diet for adults, is obtained in Britain almost solely from the cow; goat and ewe milk being only occasionally used in the preparation of cheese; whilst that of the ass is partaken of by invalids.

Referring the reader to the article DAIRY for the management and preparation of milk, cream, butter, cheese, and the like, we shall here merely advert to the respective dietetic peculiarities of these preparations. Cow's milk, when obtained from healthy, well-fed, and properly kept animals, is a very useful and valuable article of food, as well for adults as for children. Its principal drawback, according to Pereira, is the difficult digestibility of its fatty constituent, or butter—an objection, however, which can be got rid of by using it in the *skimmed* state. Under the name of *milk-diet*, it is extensively employed in conjunction with bread, oatmeal, rice, sago, potatoes, and other farinaceous substances, and forms in every case a readily assimilated and nutritive aliment. *Cream* consists of butter, curd, and serum or whey, and though less digestible than milk, properly so called, is not so liable to this objection as butter. Fresh *butter* is more easily digested than salt; and whether salted or fresh, preference is always to be given to that most recently prepared. *Whey* is chiefly composed of water and lactic acid, with a slight

proportion of caseine, butter, and sugar. It is therefore very slightly nutrient, but forms an excellent diluent in inflammatory complaints, and also gently promotes the secretions. *Butter-milk*, as containing the caseine, the sugar, and the salts of milk, must possess nutritive properties. It is deserving of wider adoption, both as an article of diet, and as a cooling and agreeable beverage. *Curd* is less easily digested than cream; but more so than butter. It consists mainly of caseine, and this from fresh milk yields 54·83 carbon, 7·15 hydrogen, 15·63 nitrogen, and 22·39 oxygen and sulphur. *Cheese*, or caseine dried, and having probably undergone some chemical change during the process of 'ripening,' is generally very difficult of digestion. It usually contains a considerable proportion of the fatty part of the milk, and in some cases is made almost entirely from cream. The impunity with which many persons can eat toasted cheese may be partly attributed to the mustard, &c., eaten along with it, although the cooking has much to do with the greater digestibility. Cheese made from cow's milk is more easily digested than that from goat's milk; and the richer or more oleaginous the cheese, the more easily is it digested. Ripe cheese is preferable to that which is green or immature, and also to that which is partially decayed. In whatever stage, cheese should be eaten with caution, as apt to produce not only indigestion, but crudity and consequent irritation in the intestines. It will thus be observed that none of the artificial or secondary preparations from milk possess its own bland and generally unobjectionable character, and this arises from the fact of their being concentrated forms of certain principles, while in milk these principles are mingled and diluted in right and natural proportion.

Animal fat, like the oil of vegetables, consists essentially of carbon, hydrogen, and oxygen; and therefore, when taken as food, can supply only respiratory or heat-forming matter. Containing about 80 per cent. of carbon, *heat-producing* is its proper function, and thus is explained the fact why the inhabitants of cold climates can consume with impunity so much of this aliment. All fatty matters are digested with difficulty, and are apt to irritate and derange the stomach and its functions. The fat of different animals, however, differs in point of digestibility; and, what is more curious still, differs also according to the part of the animal from which it is taken. The digestibility of fat is much affected by modes of cooking; it is also greatly modified by the action of vegetable acids and of common culinary salt.

MINERAL FOOD.

It has been already mentioned that man derives little of his food directly from the mineral world. No doubt all plants and animals contain a certain amount of saline and earthy ingredients, which are indispensable to healthy aliment; but those are indirect products, and are always taken into account when estimating the relative dietetic value of vegetable and animal compounds. In fact, the only substances obtained directly from the inorganic kingdom, and consumed in large quantities, are water and salt—two substances as necessary to existence as the air we breathe. The former, as has been seen, enters largely into the composition of every species of food; it acts as a solvent and diluent in all cases, and permeates everywhere the tissues to whose subsistence and growth it administers. The latter, though usually taken as a palatable condiment, is really essential to the maintenance of health and vitality, and accordingly appears as a constituent of the blood and the tissues elaborated therefrom.

Water, as consumed by man either as a beverage or as a constituent of his food, is generally in a fresh state; that is, contaminated as little as possible by foreign ingredients. The nature and constitution of water have been already detailed under the heads CHEMISTRY and SUPPLY OF WATER: all that is necessary to be here observed is, that the supply for dietetic uses should be freed from all mechanical impurities, and from all chemical impregnations, which may render it unpalatable, unsuitable for culinary purposes, or detrimental to the system of the consumer. Absolutely pure water is not found in nature, nor does it indeed seem to be required by the animal economy. It is only pure when distilled, and in this state it is neither pleasant to the taste nor wholesome. The purest waters always contain some amount, however small, of common salt, lime, iron, and other saline matters; as also organic matter. It is only when these foreign substances exist in large amount that water becomes objectionable. Good water is generally known by its softness, its limpid and somewhat sparkling appearance, its agreeable flavour, and its non-liability to become putrid. Its softness it acquires from the absence of saline or mineral ingredients, its sparkling aspect and agreeable flavour from the carbonic acid which it has absorbed from the atmosphere, and its resistance to putrescence from the comparative absence of animal or vegetable matter. By filtration, which is now generally practised, all mechanical impurities can be got rid of; but for the removal of the more objectionable chemical impregnations, boiling, or the admixture of chemical re-agents, is required.

The ordinary sources of fresh-water are rains, springs, rivers, lakes, and wells; and according as it is obtained from one or other of these sources, so is it characterised by peculiar properties. *Rain-water*, if collected in mountain districts, far from human dwellings, is perhaps the purest of all; but if collected in the neighbourhood of towns, it is found to be largely impregnated with soot and other extraneous substances; and the rapidity with which it putrefies, demonstrates the presence likewise of organic matter. Being soft, it is valued by the housewife for washing; but is unfit for internal or culinary purposes without undergoing rigid filtration. Unimpregnated with mineral substances, its action on lead is more rapid than that of other waters, and it should never, therefore, be kept in lead cisterns. All *spring-water* is less or more impregnated with the substances through which it has percolated to the surface; but with the exception of those commonly termed 'saline' or 'mineral'—and which are noticed under MEDICINE—most springs yield water of sufficient purity for domestic purposes. Those issuing from the primitive and igneous rocks, or from extensive beds of sand and gravel, are generally the purest; those from the carboniferous and other secondary strata are not so free from impurity. *River-water*, which is an accumulation of rain and spring water, is often well fitted for human purposes. Its impurities are both of a mechanical and of a chemical kind; the former may be removed by careful filtration. Much, however, depends upon the soil and district through which the river flows; meadows, morasses, and forests yielding organic matter, and factories and towns bequeathing heterogeneous impurities, not to be got rid of by any ordinary process. Water drawn from fresh *lakes* is less turbid than that from rivers; but is always—unless from deep mountain tarns—more largely impregnated with vegetable and animal matter. *Well* or *pump water* is that obtained by boring or by sinking shafts into rocky strata. It must, of necessity, like spring-water, partake more or less of the mineral ingredients through which it percolates; and is not unfrequently injured by the pumps, pipes, and other apparatus by which it is raised. Such are the ordinary sources from which man derives his dietetic waters; and it were greatly to be desired that more efficient modes of purification, as well as abundance of supply, were more generally adopted in reference to our towns and cities, which, with few exceptions, have neither quantity nor quality to boast of.

Respecting the alimentary functions of water, Dr Pereira, after remarking that it is the natural drink

of all adults, observes: 'It serves several important purposes in the animal economy: *Firstly*, It repairs the loss of the aqueous part of the blood, caused by evaporation and the action of the secreting and exhaling organs; *Secondly*, It is a solvent of various alimentary substances, and therefore assists the stomach in the act of digestion, though if taken in very large quantities, it may have an opposite effect, by diluting the gastric juice; *Thirdly*, It is probably a nutritive agent —assisting in the formation of the solid parts of the body. It has not, indeed, been actually demonstrated that water is decomposed in the animal system; or, in other words, that it yields up its elements to assist in the formation of organised tissues; yet such an occurrence is by no means improbable. It appears from Liebig's observations, that the hydrogen of vegetable tissues is derived from water; and it is not probable that the higher orders of the organised kingdom should be deficient in a power possessed by the lower orders. Dr Prout appears to admit the existence of this power, but thinks that it is rarely exercised by animals. The water which constitutes an essential part of the blood and of the living tissues, assists in several ways in carrying on the vital processes. "In the blood," says Prout, "the solid organised particles are transported from one place to another; are arranged in the place desired; and are again finally removed and expelled from the body, chiefly by the agency of the water present." It is from water that the tissues derive their properties of extensibility and flexibility. *Lastly*, This fluid contributes to most of the transformations which occur within the body. As a solvent, it serves not only to aid digestion, but also to effect other changes, as, for example, the conversion of uric acid into urea, and sugar or starch into sugar of milk and diabetic sugar. So, also, the hydrochloric acid of the gastric juice, and the soda of the blood and bile, are derived from common salt (chloride of sodium) by the aid of water.'

Salt.—Referring the reader to our article on MINING AND MINERALS, for an account of the modes of procuring and preparing this indispensable article, we shall here strictly confine our remarks to its dietetic or alimentary importance. 'By virtue of its chlorine,' says a popular authority, 'salt largely promotes the functions of the stomach and bowels in assimilating the food; by virtue of its soda, it greatly subserves the uses of the bile in the economy; and in its every action —whether by means of its separated constituents, or in its combined state, serving probably to maintain the blood in its singularly compound and yet homogeneous condition—is shewn to be great on all the functions and conditions of the body. There can be no question, however, that even salt may be too much or too little used in the food: that in the one case, the tissues and the expending organs are too much stimulated; in the other case, the system is unduly, and not without serious risk, deprived of that agent, by which so large a share is performed in the nutrition of the body; and which in itself, by its ultimate elimination from the body in the several excretions, probably serves to keep up the action of the excreting organs, and promotes the disintegration and throwing off of the effete matters, no longer fitted for the purposes of the economy, and which could not be retained without injury. The less readily assimilated the articles may be, and the less of saline matter contained in them, the more essential is salt as a part of the food; hence the oily articles of food, and the purer forms of the starchy principle, when largely used as means of nutrition, require usually more salt to be eaten with them than the more ordinary and less pure forms of vegetable or even animal diet. And yet animal diet of any kind, probably from its putrescent tendency, if not mixed with vegetable food in sufficient proportion, is found to require a large mixture of salt with it, for the maintenance of health and strength.' The amount of salt consumed by a full-grown person has been estimated at sixteen pounds a year, or about five ounces a week; but of course this estimate will vary exceedingly, according to the tastes and habits of individuals.

All the varieties of salt, whether small-grained, like the *basket* or *table salt*, or in large crystals, like the *bay* and *fishery salts*, consist essentially of chloride of sodium, which is composed of 60 per cent. chlorine and 40 sodium. The salt of commerce, however, is never found absolutely pure, being less or more contaminated with salts of lime and magnesia, as well as insoluble matter. Thus an average of foreign bay-salts yielded to analysis 3½ per cent. of such impurities; British salt from sea-water upwards of 4 per cent.; and that from English rock-salt somewhat more than 1½ per cent. The purer salt is, of course the more wholesome will it be as an article of diet, and the more effectual for the purposes of pickling and curing provisions.

BEVERAGES.

Writers on dietetics are in the habit of classifying drinks or beverages according to their sensible, chemical, or medicinal properties. Thus we have—1. Mucilaginous, farinaceous, or saccharine drinks; 2. Emulsive or milky drinks; 3. Animal broths, or drinks containing gelatine and osmazome; 4. Aromatic or astringent drinks; 5. Acidulous drinks; and, 6. Alcoholic and other intoxicating drinks. Water, however, is the only true natural beverage: it forms the basis of the whole of the above—the other constituents being but infusions, decoctions, and solutions of solid elementary substances already described. Being reduced to a liquid form, the alimentary action or effect of these substances is much facilitated, and thus, in point of easy assimilation, beverages are immensely superior to solid food. In certain cases, therefore, it is advisable that diet should be taken in this form; not only on account of its ready assimilation, but from the accuracy with which it can be reduced to the necessary strength. In all cases, however, of healthy existence, food in a solid form is indispensable, and beverages are to be regarded simply as diluents, demulcents, and correctives. Setting out with this view, and following the above distinctions, we shall now briefly allude to the more abundant and familiar beverages—adopting as authorities Liebig, Pereira, and Robertson:

1. The mucilaginous, farinaceous, and saccharine drinks are perhaps the simplest, next to water. They are merely solutions, infusions, or decoctions of substances already described, and are known by such terms as *gum-water*, *toast-water*, *sugar-water*, *barley-water*, *mucilage of rice*, and *gruel* from oats, sago, arrow-root, or tapioca. They are all very slightly nutritive; and are used chiefly in the sick-chamber as demulcents and diluents. Toast and barley waters are placed by the faculty at the head of this division.

2. Emulsive or milky drinks are such as hold in suspension any oily or fatty substance in a finely divided state. *Animal milk* (already described) is at the head of this section; others, as *milk* and *sirup of almonds*, fall more properly to be noticed under MEDICINAL PREPARATIONS.

3. Broths and soups, or drinks containing gelatine and osmazome, are usually prepared from beef, mutton, veal, and chicken. A number of receipts are given for their preparation in the article COOKERY; the rationale of their aliment has been already described. Boiled meat of good quality yields kreatine and osmazome, coagulated albumen, gelatinous cellular tissue, fatty matter, saccharine matter, some salts and water; and to prepare a soup so that none of these may be

dissipated and lost, is the chief point requiring attention. When pot-vegetables, as turnips, carrots, onions, barley, &c., are used, of course these communicate new principles to the liquid—as mucilage, sugar, azotised products, volatile oil, and salts. Extract of the pure or lean meat is always preferable for invalids and convalescents —*beef-tea* and *chicken-broth* being the most highly recommended.

4. Of the aromatic and astringent drinks, tea, coffee, and chocolate are pre-eminently the most familiar. 'We shall never, certainly, be able to discover,' writes Baron Liebig, 'how men were led to the use of the hot infusion of the leaves of a certain shrub (tea), or of a decoction of certain roasted berries (coffee). Some cause there must be, which would explain how the practice has become a necessary of life to whole nations. But it is surely still more remarkable that the beneficial effects of both plants on the health must be ascribed to one and the same substance, the presence of which in two vegetables belonging to different natural families, and the produce of different quarters of the globe, could hardly have presented itself to the boldest imagination. Yet recent researches have shewn, in such a manner as to exclude all doubt, that *caffeine*, the peculiar principle of coffee, and *theine* that of tea, are in all respects identical.' The fact is certainly striking enough, and all the more so that cocoa or chocolate also yields a principle (*theobromine*) identical, or all but identical with theine and caffeine. These principles furnish elements precisely the same as those of the bile; hence their effect on the processes of secretion, on nutrition, and vitality.

Tea is usually distinguished as *black* or *green:* the former including such marketable varieties as Bohea, Congou, Souchong, Caper, and Pekoe; the latter, Twankay, Hyson, Imperial, and Gunpowder. Of the black teas, Pekoe is one of the best; of the green, Gunpowder. When subjected to analysis, they all yield less or more volatile oil, chlorophyle or colouring matter, wax, resin, gum, tannin, theine, albumen, lignin, and extractive matter. The dietetic and medicinal properties of tea are thus detailed, throwing out of view the qualities usually imparted by the addition of sugar, milk, or cream:—It acts on the system as a stimulus or a sedative, according to the strength of the infusion that is taken. When taken in smaller quantity, its effect is, in general, simply and in a small degree sedative, even in the first instance; when used in larger quantity, its primary action is decidedly that of a stimulus. Its well-known effect of inducing wakefulness illustrates this. To many people, when taken late in the evening—and in some when taken strong at almost any time—it produces a very sensible degree of stimulation, and a state of sleepless excitability. Besides inducing wakefulness, tea seems to sharpen the mental faculties, and perhaps, in an especial degree, the imagination. Green tea has, generally speaking, more stimulating, black tea, more sedative properties. The stimulating effects are, however, always and necessarily followed by sedative effects, which may amount in extreme cases to depression, or even to a degree of narcotism; and in most cases it acts as a narcotic on the organs of excretion, producing more or less visceral torpidity and sluggishness. To the man who has a sufficiency of nourishing and wholesome food, the use of tea in moderate quantities, and at proper times, cannot be said to be ever followed by unpleasant or unsatisfactory consequences. If taken in excessive quantities, tea becomes decidedly debilitating to the nervous system, affecting it much in the same way as any other stimulant and narcotic. But though tea, when used in moderation, is serviceable to the individual who takes a sufficient quantity of nutritious food, unquestionably serving some important purpose, in completing and perfecting the last stages of digestion; and although, under such circumstances, the use of tea is not injurious, this is by no means the case when the aliment that is taken is deficient in quantity or of too poor a quality. Under such circumstances, tea acts on the nervous system to a degree that is often productive of disorder, and which probably sometimes leads to disease. The effect of tea on the second stage of digestion, and probably on the secretion of the bile, points out and explains its value when taken about three or four hours after the principal meal of the day, and illustrates the well-known anxiety of the dyspeptic for tea-time, and the comparative comfort he enjoys after this beverage, which is aptly said 'to cheer, but not inebriate.' Taken at the same time as a heavy meal of food, or such a meal as contains a large proportion of the day's alimentary supply, tea may prove to be too much of a diluent, or too directly narcotic; and in some cases may rather retard the primary digestion than otherwise. This, however, depends very much on the quantity and the strength of the infusion made use of. Green tea, although said to be used almost exclusively in some countries, is found to be much too narcotic and stimulating for exclusive use in this country, and is necessarily forbidden to most invalids, from its evidently enervating effects.

The *Coffee* of commerce is the seed of a berry-bearing tree or shrub, found originally in Arabia, but now extensively cultivated in all tropical countries. It is usually distinguished by the place of its growth—as Mocha, Jamaica, Mountain-Jamaica, Demerara, Ceylon. Raw coffee can be kept for any length of time without deterioration—indeed, the older the better; but on being roasted, it develops a fragrant and aromatic principle, which is extremely volatile. Roasted coffee should therefore be ground and used as speedily as possible. Coffee yields to analysis caffeic acid, tannic acid, caffeine, wax, resin, gum, albumen, lignin, extractive matter, and salts of lime, magnesia, and iron. Its dietetic properties and peculiarities are thus detailed by the preceding authority: Used in infusion or decoction, coffee is more nutritious than tea, but is more difficult of digestion. Whether owing to the tannin, which the roasted coffee is said to contain, or to the aromatic oil, or the mucilage, or the bitter extract, or to the combination of these different constituents, coffee deranges considerably the stomachs of some people, and is usually somewhat difficult of digestion to invalids and to those who are more seriously dyspeptic. It is probable that this is not referable to the aromatic principle, as the best coffee, which contains more aroma, is less likely to disagree than the commoner sorts. The infusion is usually less apt to disagree than the decoction, unless the latter have been most carefully clarified. The consequence of coffee proving to be of difficult digestion, is rather to produce considerable acidity than to give rise to any other marked dyspeptic symptom. Supposing that coffee does not disagree, which in the healthy and strong it seldom does, it is a peculiar and decided stimulus, quickening the circulation, promoting the secretions and excretions, very perceptibly warming the system and elevating the spirits. Supposing that the powers of the digestive organs are adequate to its complete assimilation, coffee, from being much more nutritious, and more decidedly restorative to the system, forms a better addition to other articles of food that are taken at breakfast than tea. If its ready digestibility be suspected, the question of its being mixed with sugar, and the known difficulty with which sugar is digested, should be considered before coffee is pronounced to be unsuited to the individual. The addition of milk to coffee adds much to its nutritiousness, diminishes in some degree its directly stimulating effects, and seldom makes its digestion more difficult. As to the addition of *chicory*—the roots of the wild succory, or endive, dried and ground—now so commonly practised, medical authorities are rather in favour of a moderate admixture than otherwise. The chicory-root is perfectly wholesome, contains no alkaloid or oil, and only a small amount of resinous and narcotic

matter. When added in small quantities, it rather improves the flavour of coffee, apparently combines with, or neutralises its oil, and altogether renders it less difficult of digestion.

Cocoa is derived from the seeds or nuts of the chocolate-tree (*Theobroma cocoa*), a native of tropical regions. The seeds grow in pods, and are prepared for use by being roasted, deprived of their husks, and ground. Cocoa is either used in the form of the ground seeds, simply made into a decoction; or these are ground into a paste, mixed with cloves, cinnamon, vanilla, &c., forming *chocolate*. In either form, cocoa is described as oleaginous, and somewhat acrid, and is in general by no means so easily digested as tea or coffee. Still, there are many people, both dyspeptic and sedentary, with whom it invariably agrees; and this much can be said in its favour, that it is devoid of the disagreeable qualities of disturbing the nervous functions. The ground seeds are preferable to the paste or cakes, of whose composition, or, we should rather say, adulteration, we are ignorant.

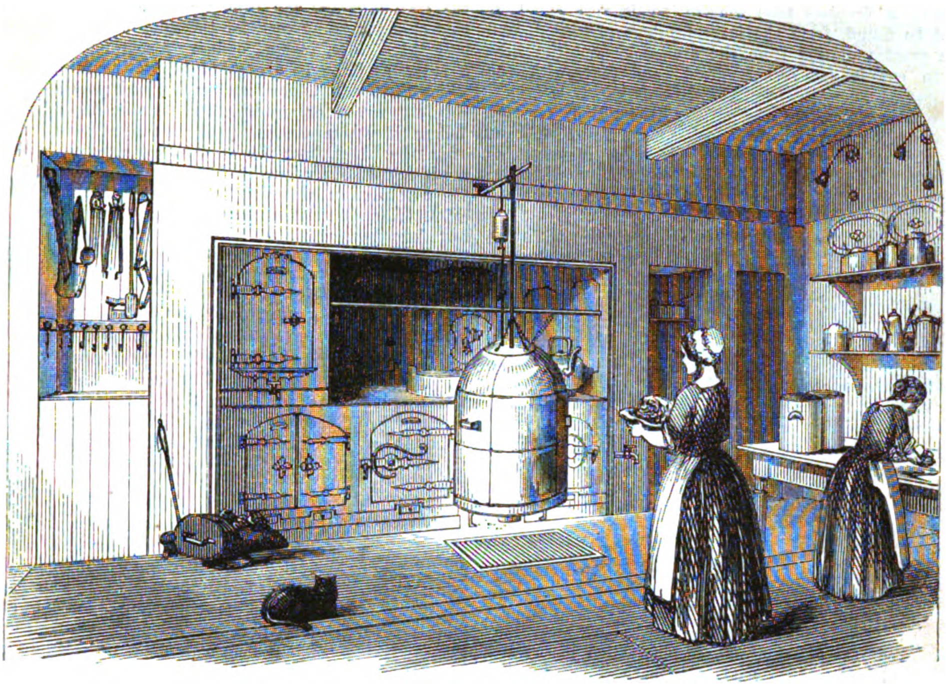
5. The acidulous beverages in common use are *lemonade*, *ginger-beer*, *soda-water*, *effervescing saline draughts*, *Seidlitz powders*, and the like. Their action being medicinal and corrective, rather than alimentary, their consideration properly belongs to a subsequent number. When prepared from the acid juices of fruits —as lemon, raspberry, apple, &c.—they form cooling, refreshing, antiscorbutic drinks, and are well adapted for hot seasons and for febrile and inflammatory cases. When compounded of some alkali and acid, like the common effervescing draughts, they are also slightly aperient.

6. Beverages which are the products of fermentation are usually classed as *spirits*—brandy, gin, whisky, and rum; *wines*—port, sherry, claret, champagne, &c.; *liqueurs*—embracing all the sweet or home-made wines; and *malt liquors*—ale, porter, and beer.

Referring the reader to CHEMISTRY APPLIED TO THE ARTS, for the theory and principles of fermentation, we shall here merely allude to the alimentary or dietetic effects of these well-known, and in many cases, too largely consumed beverages. *Alcohol*, or the leading principle in spirits, consists of carbon, hydrogen, and oxygen; it contains no nitrogen, sulphur, phosphorus, or other ingredient capable of administering to growth or nutrition. Its function is that of a heat-former; it is merely an element of respiration, serving to support the temperature of the body. But in subserving this purpose, it stimulates, excites, and, if taken in any quantity, intoxicates; and the question for those in search of animal heat simply resolves itself into this —Can we not gain our end by means more simple, natural, and less dangerous? It has been well remarked, that 'though alcohol evolves heat in burning, it is an obnoxious fuel. Its volatility, and the facility with which it permeates membranes and tissues, enable it to be rapidly absorbed, and when it gets into the blood, it exerts a most injurious operation, before it is burnt in the lungs, on the brain and the liver. Though, by its combustion, heat is evolved, yet, under ordinary circumstances, there are other better, safer, and less injurious combustibles to be burned in the vital lamp.' It is only, indeed, as a restorative and corrective that its use is at all admissible; and there can be no doubt that in cases of extreme exertion and privation of food, the cautious and moderate dietetic use of spirits has on many occasions proved invaluable. *Brandy*, derived from the distillation of wine, is perhaps the least objectionable form in which alcohol is administered. Its constituents are alcohol, water, volatile oil, a minute quantity of acetic acid, œnanthic ether, and colouring matter. It is distinguished from other ardent spirits by its cordial and stomachic properties. *Rum*, distilled from molasses and sugar skimmings, is very similar to brandy in its effects, but more heating, and more disposed to cause sweatings. *Gin*, obtained from corn-spirit, and flavoured with juniper, sweet flag, &c., is, owing to the oil of juniper it contains, more powerfully diuretic than either brandy or rum. *Whisky*, also a corn-spirit, agrees in most of its properties with gin, but is somewhat lighter, and more stomachic.

Wine is the general term applied to liquors prepared by the vinous fermentation of the juice of the grape. 'The peculiar qualities of the different kinds of wine depend on several circumstances; such as the variety and place of growth of the vine from which the wine is prepared; the time of year when the vintage is collected; the preparation of the grapes previously to their being trodden and pressed; and the various manipulations and processes adopted in their fermentation.' Though thus varying, and known by a thousand names, the general constituents of all wines are—water, alcohol, volatile oil, sugar, gum, tannin, tartrate and bitartrate of potash, acetic acid, extractive and colouring matters, and carbonic acid, in the effervescing varieties. The amount of alcohol in wines is exceedingly varied: in claret, for example, it seldom exceeds 7 or 8 per cent. by weight; while in ports and sherries it ranges from 12 to 18 per cent. As to the dietetic properties of wine, Dr Paris asserts 'that there exists no evidence to prove that the *temperate* use of good wine, when taken at *seasonable* hours, has ever proved injurious to *healthy* adults.' Dr Pereira is by no means disposed to question this assertion, qualified as it is; but maintains, on the other hand, that 'for healthy individuals wine is an unnecessary article of diet. It may prove,' he continues, 'a valuable restorative when the powers of the body and mind have been enfeebled by fatigue; but, on the other hand, it cannot be denied that the most perfect health is compatible with total abstinence from wine; and that the habitual employment of it, especially by the indolent and sedentary, is calculated in many instances to prove injurious. Disorders of the digestive organs and of the brain, gout, gravel, and dropsy, are the maladies most likely to be induced or aggravated by the use of wine. Intoxication, in its varied and lamentable forms, is the effect of the excessive use of it.'

Malt liquor is the generic term for all fermented infusions of malt flavoured with the bitter principle of hops. Normally, they ought to contain less or more of alcohol, starch, sugar, dextrine or starch-gum, extractive and bitter matters, fatty, aromatic, and glutinous matters, lactic acid, carbonic acid, salts, and water. They are, however, often largely adulterated—molasses and other wash being used for malt, quassia substituted for hops, flavours imparted by capsicum, ginger, and coriander; and intoxicating qualities conferred by cocculus Indicus, nux vomica, and opium. Keeping out of view these adulterations, the genuine liquors are fitted by their constitution to quench thirst and act as diluents, to yield heat and nutrition, and to operate as tonics and stimulants. The only drawback to their use in large quantities is the intoxicating effect of their alcohol—common beer containing about 1 per cent. by measure of this spirit, porter from 4 to 6, and strong ale from 6 to 8.



Kitchen, with Close Range.

PREPARATION OF FOOD–COOKERY.

COOKERY is the art of preparing food. Much of our daily comfort and health depends on the way in which food is prepared. Every housewife may not be able to procure the finest kinds of food, but by attention, activity, cleanliness, and neatness, a great deal may be done to make even the plainest fare palatable and wholesome.

Boiling and Stewing Vessels are now to be had of every size and description; the best kind—called goblets in Scotland, and sauce-pans in England—are those made of iron, well tinned inside. It is convenient to have one or two of the very smallest dimensions, made of block tin; and also to have several to be kept for delicate stews or preparations, for which purposes those lined with delf are preferable. It is likewise advantageous to have a few shallow sauce-pans to be used for stews, or where little liquor is required; also one large fish-kettle, with a flat drainer to place below the fish in boiling, and for lifting to the dish when done. All the vessels should have tightly fitting tin or iron covers; and one or two should be fitted with perforated apparatus for steaming.

The *Kitchen-range* forms the most important part of the cooking apparatus, and without one that does its work well, we cannot have our food prepared satisfactorily. Great attention should therefore be paid in choosing one and fitting it up. As a very large proportion of those in use is faulty, it will be useful to give a few hints on their constructions, as well to those who may have to purchase new ones, as to those who wish the ranges already in their possession improved. And first, in regard to the fire, in a moderate establishment, the *open fire* is to be preferred to the *hot plate*, because it is simpler, and consequently cheaper; and also because, with some slight modifications which will be mentioned, it is really, in some important respects, more economical and efficient. The great objection to an ordinary open kitchen-fire is, that it consumes a great quantity of coals, and yet can only with difficulty be got to give the 'quick' sustained heat that is required for roasting and other culinary processes. The reason why a quick fire is essential to good roasting, is obvious. When we boil properly a leg of mutton, we put it into water brought to the boiling temperature, in order that the outer layer of albumen may be rapidly coagulated, and may thus form a crust which will retain the internal juices and savour of the meat; and so also, in roasting, if we wish these retained, and the meat properly done, we must have the fire quick before the meat is exposed to it. A proper heat is most effectually obtained, at the same time that a great saving in coals is effected, by using a *fire-brick*. This should be placed at a distance of not more than five or six inches behind the bars of the grate, to secure its great power in radiating heat, and, at the level of the bar which folds down, it should be shaped thus (as seen from the side), so that pots may rest either on the ledge, A, or on the top, B. The fire can thus be made broader at top when required. The thickness of the fire-brick should be about three inches, or, where there is a boiler behind, the shape can be made to correspond to it; and it will be found that the heat communicated to the boiler at the side, will be quite

Fig. 1.

sufficient to keep the water in it hot. Although the size of a fireplace thus constructed is very small, it will be found, from the large frontage presented, and the great radiation from the fire-brick, that the heat given out is surprisingly great; and that, with the 'dispatch' where the fire is small, or, where it is larger, with a tin screen to go before the fire, and the common simple apparatus of a spit, with two horizontal balls attached to a skein of worsted, almost all roasting processes can be managed easily and to perfection; for meat cooked in this way is always sweeter than when done in the oven.

The width of the fire, of course, will vary with the size of the range. Its breadth from the bar to the top of the fire-brick, B, is six or seven inches; which from the great heat given out, will be found amply sufficient for boiling processes. Increased accommodation for these and other purposes can be got by having a movable 'trevet'—on the side next the boiler, where there is one —on which can be placed small pots; and by having a firm bar of iron to go across the fireplace, immediately above the fire, at a height of about two feet above it. This is fixed in the mason-work of the two sides of the chimney, and three or four hooks are attached to it, from which pots can be suspended. Where this arrangement is adopted, the pots for stewing, &c., should have handles that can be attached to the iron bar. A good kitchen-range should have a boiler on one side—extending, if wished, behind the fire—and an oven on the other side. The frontispiece represents a very superior kitchen-range, fitted up with ovens, hot-plates, &c.; the fireplace, which is very small, is so arranged that a dinner may be cooked for thirty people, besides which it supplies enough of heat to keep water for a bath at a sufficiently high temperature. The apparatus is so constructed that the operations of boiling, roasting, stewing, frying, baking, and steaming may be carried on at one time. This range, however, is costly, and can only be recommended for the kitchens of the opulent classes; it is manufactured by Henry Goddard of Nottingham, who has devoted much time and attention to the subject. The proper heating of the oven, from the faulty construction of those seen in Scotland at least, is a matter of great trouble, and even difficulty, to the housewife. By attention to a few simple arrangements, a great heat may be obtained for it without any other fire than has been described; so great, indeed, that the top of it can be made, when wanted, to serve as a hot plate, at the same time that it is always ready for use at a minute's notice. To make this obvious, we shall, in a few words, describe the alterations we had made on one of a faulty construction. The range which came into our possession was of the common make, in which the oven had a fireplace beneath it, but with no communication with the fireplace of the range, though on the same level. It had been for years totally unworkable. All that was done to convert it into a splendidly working oven, which has been in constant use for many years, without once going out of order, was as follows: The fireplace under the oven was built up with care to the level of the fire-grating, and the ash-pit closed; a free opening was made from the fireplace of the range into that under the oven, and a sheet-iron tube, six feet in height—four or five feet will answer—was run up within the kitchen-chimney, from the top of the oven-chimney. This simple arrangement, it will be perceived by those conversant with such matters, gave a 'draught' of hot air through the range-fire, *when all other access to the external air was carefully closed;* and thus the oven can be kept constantly ready for use, without either cost or trouble. By adding to the fire occasionally, near the opening under the oven, a few pieces of fresh coal, a constant very high temperature can be kept up; which may be moderated, by opening for a short time the door under the oven. The most common cause of difficulty in heating the oven in defective ranges, arises from want of length, and consequent want of draught, in the oven-chimney, and from the tube forming part of this chimney being cast, for the sake of economy, with only three sides, instead of being a complete square, or circular, as it ought always to be, as the mason-work which is trusted to for forming the back portion of the tube, can never for any length of time be depended on. Where there is no opening from the range-fire under the oven, the latter, from the trouble connected with heating it, is practically found to be almost useless. Whatever the construction, therefore, this opening should always exist. Ranges constructed upon the principles which have been mentioned, and called 'The Self-acting Hot-air Kitchen-range, with Fire-brick,' may be ordered from any ironmonger. A small one costs about £2, and larger sizes cost in proportion.

Before entering upon the subject of cookery in a systematic form, it has been thought that it may be useful, especially for the working, and some of the middle classes, to mention a few principles of cookery, and to give some plain practical directions for the preparation of the homely fare which may be supposed to be the daily food of such families. This department we shall designate

COTTAGE COOKERY.

In Scotland, the dish almost universally used for breakfast by the working-classes and for children is oatmeal *porridge*, the oatmeal being rougher in the grain than is generally used in England. The fault commonly committed in making this excellent and wholesome article of food is in not boiling it sufficiently. Three-quarters of an hour's boiling is required to break down the meal, and render it properly digestible. Where the water is 'hard,' a very small bit of washing-soda accelerates the process; but this requires to be cautiously used. Churn or sweet milk, or a mixture of the two, is used along with the porridge.* Among the middle classes, the plate of porridge is often followed by a cup of coffee, which is calculated to correct the slight sluggishness which some persons feel after taking porridge alone.

Coffee to breakfast is now the article most commonly used by the middle classes in this country. It is preferable to tea when the latter is taken in the evening. Strong tea twice daily, for nervous persons especially, amounts to a species of dissipation, and produces upon some very unpleasant effects. The stimulus from taking coffee is more gentle and diffused, and is quite as long continued. To prepare really good coffee, is found by many housewives to be rather a difficult matter, and yet it is very easy if a few simple directions are attended to. The object in view is to get the coffee to impart to the water poured on it the slightly bitter and the aromatic principles which it contains, and to lose none of these. This is best done by pouring on the coffee in the coffee-pot boiling water, accurately closing the cover of the coffee-pot, and fixing a nozzle on its spout, and then placing the pot on the fire, and just allowing the water to boil. The moment steam appears, the coffee is made, and the pot must be taken off the fire. Coffee made in this way has the one disadvantage, that it is not so clear as could be wished. To obviate this defect, the white of an egg or isinglass is sometimes used; and in France a percolator is fitted to the top of the coffee-pot. The first, however, is troublesome, and the second is expensive, as a large quantity of coffee must be used to insure a sufficient extract of its qualities. There is a form of coffee-pot which has the percolator placed *in* and not *on* it, and which thus obviates the objection mentioned. It is of this

* For economy, some years since, treacle-beer was substituted in one of our penitentiaries for the milk; but this had to be discontinued, as an alarming outbreak of scurvy took place in consequence of the change.

construction. A is the coffee-pot with the nozzle fixed; B is a section of the same with the percolator, F, inserted, which easily slips into the coffee-pot, and rests on plugs at C, C; D is a small upper percolator, with a curved handle, which fits into the top of F, also resting

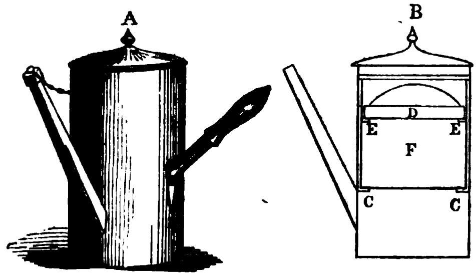


Fig. 2

on plugs, E, E. When coffee is made in this pot, the percolator, F, is placed in its situation within the pot; all the openings in the percolator are covered gently with coffee; the small upper percolator, D, is put in its place, and boiling water is poured through it on the coffee, in such quantity as may be wished. The cover and nozzle are immediately fitted on the pot, which is placed on the fire until steam appears at the spout and cover, when it is instantly withdrawn. In use, this pot is found to be very simple, and with it a pure and very fine coffee may always be had.* A fourth of foreign chicory imparts body and improves the quality of the coffee; and if these have not been got within a day or two after being roasted, they should be heated together over the fire in an iron pot before being used. Mr Soyer has made the important observation, that coffee thus heated, and tea heated in the teapot for ten minutes before infusing, are both in consequence made to part with their aromatic properties more readily. For breakfast, one-third of boiled milk should be used with the coffee, the latter of course being made proportionately strong; or cream alone, or with the milk, may be used when the coffee is wished richer. In infusing *Tea*, besides slightly heating it as mentioned, most housewives are aware that where the water is hard, a small quantity of carbonate of soda assists the process.

Fresh rolls—in winter, they should be heated in the oven—are now generally used among the middle classes, where there is the convenience for getting them. As relishes to the tea or coffee, the best are good salt, red, kippered, or Nova Scotia herrings, a Finnan haddock, an egg, a bit of fried smoked bacon, tongue, &c. In June, and the two or three following months, one of the great annual treats of this kind enjoyed by the population in the towns in the west of Scotland is the delicious Loch Fyne herrings, very slightly salted. To breakfast, or with young potatoes to dinner, almost nothing can be finer. They generally require to be steeped in cold water for a night, and are then used boiled, or 'reisted'—that is, hung up and dried, and done on the gridiron. This cheap and simple treat should be more extensively known to the working-classes. Among the most delicate of breakfast-dishes, when in season, are the 'rizzared' whitings or small haddocks. Rizzaring a haddock means simply cleaning it, slightly salting, and hanging it up to dry for a day or two.

Dinner in this country is generally considered the most important meal. In the south, the workman must have for it his bit of roast-meat or stew, with pudding, pie, or dumpling; while in the north he rarely tastes roasts or dumplings, and is content for the most part with 'broth and meat.' Perhaps each could, for the improvement of this meal, with advantage borrow some hints from the other. The Englishman would find it advantageous to have introduced at his table the wholesome vegetable soups so largely used in Scotland, while the Scotchman would experience both variety and satisfaction from having more of the savoury dishes in which his English neighbour delights.

* One for a family may be made 9 inches high, by 5½ wide, and smaller for one or two persons. Any tinsmith can easily make them from the section given, at a price varying from 2s. 6d. to 3s. 6d.

We shall first speak of *soups* as an article of diet. In making these, we constantly see violated, in the houses of workmen, the most obvious principles of good cookery and economy, to an extent which it is positively painful to think of. Let us take, as an example, the mode in which the Scotch housewife very generally prepares her barley-broth for the family. As an old song says, 'She makes a great fire, and she puts on the pot,' well filled with water, into which are put the meat and barley, mixed with pease. The water immediately gets into a violent state of ebullition, which is continued for two hours, two hours and a half, or longer, as time may permit. To prevent the cover of the pot being blown off, from the great quantity of steam generated, it is removed, or, more usually, the 'porridge-spurtle' is introduced, so as to keep the cover partially off, and allow the contents of the pot an easy escape. After this process has proceeded for an hour or so, the vegetables are introduced, and, as violent boiling implies diminution in quantity, 'ekes' of water are made at intervals, to keep the whole up to the required amount. Now, what we have to complain of here is, that with all the violent demonstrations which the pot has for hours been making, the result to the family is most unsatisfactory, for they obtain, at considerable cost, only a watery, tasteless compound, instead of a wholesome savoury mess. No doubt, it is 'satisfactory' to the housewife, while the pot is violently boiling, to hear and see that something is being done; but she should consider that to boil such pots fast requires a good deal of coals, for which a high price has to be paid, and that, with all her fast boiling, she never makes the water one degree hotter than when it *just boils*, without giving any 'demonstrations,' and that in consequence all this noise is useless. And further, she should consider that, when her husband gives her money to buy beef, he expects that she will, in cooking it, faithfully preserve to him its nice savoury qualities, and not first diffuse these in the water, and then send them up the chimney with the steam. If she will think of this matter for a little, she will see also that the vegetables in her broth are a 'little' hard, and that there is no good reason why they should not be put into the pot at the commencement of the process, and be allowed to remain there until they become soft and pleasant to the taste, and diffuse their sweet juices through the whole compound. The result of the whole, we have no doubt, will be, if she will just give heed to a few of our 'instructions' in this and other things, that she will soon save for herself the price of several new gowns, and will make the dinner-hour a pleasant one for her husband to think of. 'Well, then,' she will say, 'how do *you* make barley-broth?' Here is the way in which we proceed:

Mutton or Beef Broth.—Take two or three pounds of a neck of mutton, or the same quantity of the shin or hough of beef, or of the flank or nineholes of beef, and put it on the fire with one gallon and a half of water—adding a bit of washing-soda, of the size of a large nut, where the water is the least hard—two tea-cupfuls of barley, and the same of dried green pease. Take also a large Swedish turnip, or two or three smaller ones, two carrots, three leeks, a moderately sized savoy or cabbage, and clean well and mince small on a mincing-board, grating portions of the carrot and turnip, and reserving some for serving with the meat. Boil the whole very gently for three and a half hours. The cover should be

kept perfectly closed, and whenever the least steam is seen to escape, the pot should be removed a little from the fire. Without strict attention to this last direction, the broth never can be properly made. Where hough or beef is used, it should previously have lain in salt for three or four days, as this improves both the broth and the flavour of the meat. A quarter of an hour before the broth is ready, add a little minced parsley. Serve the meat with pieces of the carrot and turnip, and a little of the thin of the broth as sauce. 'Greens,' so much used by the working-classes in Scotland, impoverish the broth, and should not be used if better vegetables can be got. In families where broth is much used, and where it is convenient, a supply of Swedish turnips, carrots, and onions should be laid in at the commencement of winter; and with these, and a little parsley, delightful broth can always be made.

Sheep-head Broth is made in exactly the same way as the above, the boiling being continued for four and a half hours. The head should have a pound of the neck attached to it. In Scotland, this, along with the 'trotters,' is sent to the smith's, who singes the hair with a red-hot iron. The head should then be scraped and sawn open, the internal parts well cleaned, and the whole soaked all night in water. The head and trotters should be served with pieces of carrot and turnip, and some of the thin of the broth. To preserve the true flavour of this delightful dish, it is rather particular that the 'scraping process' should not be carried too far. Part of an ox's head, which has lain in salt for a few days, may be used in the same way.

Hotch-potch is made in the same way as barley-broth, omitting the barley, and using young green pease, Turkey beans scalded and skinned, carrot and turnip, lettuces, young onions, and parsley. A neck of mutton may be used, or lamb-ribs, cut up, and served with the soup.

It is of the most particular importance, in making the above and most other soups, that sufficient time be given for the extraction and diffusion in the fluid of the juices of the meat and vegetables. Four hours, and sometimes more, are required. As many workmen breakfast at nine and dine at one o'clock, the housewife must, as soon as breakfast is over, look active, and have everything in readiness when she intends making such soups. A good plan, to save both fuel and trouble, is, where the size of the family admits of it, to have a pot sufficiently large to make broth for two days, and to heat the broth slowly on the second day, and make a hash of the meat that remains, by first taking the meat from the bones, where there are any, and boiling the latter for an hour in a little water, with onions, pepper, and salt, and then adding the meat, cut in small pieces, along with a small quantity of flour, and heating the whole together. A little curry-powder, a cheap article, which should be more known than it is at the working-man's table, makes a delightful seasoning to such a hash, to pease-soup, potato-soup, and in other ways that will be mentioned. It can either be added while cooking, or used at the table. Many think such a hash improved by the addition of a little plain vinegar, or the vinegar off pickles, where a little mace has been used among the seasonings.

A great variety of *broths* may be made upon the same principle as the barley-broth, by using different kinds of vegetables, omitting the barley, and 'lithing' them with a little flour, potato-starch, or arrow-root, &c.; and the housewife should especially study *variety* in preparing her husband's dinners.

An excellent and *economical broth*, sufficient in quantity for even a large family, may be made by taking a pound of fattish mutton, cutting into small pieces, frying slightly with lard or dripping and making a brown gravy with flour; and then adding this, along with salt, pepper, and a little sugar to the water and vegetables, and gently boiling, as directed, for three and a half hours. The sugar makes a good addition to broths, especially at the end of the season, when the vegetables have lost much of their saccharine matter.

Leek Soup.—Take two or three pounds of the shin or hough of beef, put it on in a gallon of water, with salt, pepper, and a little sugar; and boil gently, with close cover, for two hours. Clean very well, and cut into small pieces one or two dozen of large leeks, and boil for other two hours. The hough should be served with melted butter, or a sauce made of onions stewed with a bit of butter and a little flour. This can be converted into the Scotch soup called '*cock-a-leekie*' by using in addition a fowl, and adding a few prunes shortly before it is ready.

Turnip Soup.—Use the same quantity of beef and water as in the last, with one large Swedish turnip, or two or three smaller ones, two or three onions, and pepper and salt. When the turnips and onions are boiled soft, mash them through a drainer, and boil the whole very gently, with closed cover, for four hours.

Ox-tail Soup.—Take two ox-tails, cut into pieces, and put into a gallon of water, with two or three onions, a grated carrot and turnip, pepper and salt; and boil very gently, with closed cover, for four hours. The ox-tails should be served with the same sauce as is mentioned under the head of 'Leek Soup.' Curry-powder makes a good *occasional* seasoning for the last three soups.

Potato Soup.—Put on a gallon and a half of water, with salt, a bit of washing-soda about the size of a large nut, a small breakfast-cupful of roast-beef, mutton, or lamb dripping, or two pounds of a neck of mutton or of pork, or roast-beef or pork-ham bones, or any odd trimmings of meat—it is best, however, when made with fresh roast-beef dripping—three or four large onions sliced, half a stone of potatoes, cut into small pieces; and boil with closed cover, very gently, for two or three hours. When half ready, add a grated carrot. This soup, if well made, should be quite soft and pulpy, and may be rubbed through a sieve if required. Curry-powder makes its best seasoning.

Pease Soup.—Take two or three pounds of a shin or hough of beef, and put into a gallon and a half of water, with a bit of washing-soda the size of a large nut, two pounds of split pease, a moderately sized carrot and turnip, two or three onions, and a little celery-seed tied in a bit of muslin. When the carrot and turnip are boiled soft, mash, and return them to the pot. Boil with closed cover, very gently, for four hours. When ready, strain through a sieve, and serve with hard toasted bread, cut into dice, and thrown into the soup in the tureen, so as to preserve its crispness. The hough should be served with the same sauce as is mentioned under 'Leek Soup.' This soup may be made with bones or trimmings, or roast-beef dripping, the liquor a ham or any meat has been boiled in, or even without any of these, by frying the bread in plenty of lard before cutting it into dice. Its best seasoning is curry-powder. Vinegar added before serving, or at table, in the proportion of about a tea-spoonful to each plateful of soup, is thought by many to improve its flavour, and certainly promotes its digestibility. It immediately somewhat thickens the soup, apparently by acting as boiling water does when poured on arrow-root; and it removes in a great measure one great objection which many have to this fine soup—namely, the formation by it of flatus in the stomach and bowels.

Kidney Soup.—Take a pair of kidneys, cut them into slices, wash in boiling water, and dry with a towel. Have the frying-pan ready, with hot lard or dripping, into which put the sliced kidneys, two handfuls of flour, a few onions, a dessert-spoonful of Jamaica pepper, and a little black pepper and salt. Stir with a spoon, and brown nicely. Cut into very small pieces; add this to a gallon of water, and grate into it half a carrot and the same size of turnip, and boil with closed cover very gently for four hours. If wished particularly good, a pound or so of hough of beef may be added;

but if plenty of dripping is used, this is not required. With less water and flour, and omitting the carrot and turnip, this makes a delightful stew.

Fish Soup, or '*Crappit Heads*.'—This favourite Scotch dish is made with two or three very fresh middle-sized haddocks. Clean well, cut off the heads, and cut the bodies into three pieces. Mince a few small onions and a little parsley, and mix with a large handful of Scotch oatmeal, a quarter of a pound of butter, a little pepper, and a very little salt. Work this into a paste without water, stuff the heads and the upper parts of the bodies with it, and tie firmly with a bit of thread. Put into four quarts of water, and boil gently for half an hour. If any of the paste is left over, it should be made into balls, and boiled along with the fish. Serve in a tureen, and eat with potatoes.

In hot summer weather, lighter soups than those that have been mentioned are grateful. A good one is

Veal Soup.—Take a good-sized knuckle of veal, and put it on in four quarts of water, with an onion or two; and when it has gently boiled an hour, add two tea-cupfuls of rice, and let it simmer for other two hours. A quarter of an hour before it is ready, add a little minced parsley. Serve the veal with melted butter and parsley.

In such weather, also, curdled milk, with or without cream, or rice and milk, make pleasant varieties. Cayenne or black pepper makes an agreeable seasoning for the curdled milk.

Rice and Milk.—Take a pound and a half of rice, and wash till the water runs clear from it. Put it on in as much water as will cover it an inch above the rice, with a little salt. Let it simmer very slowly with a closed cover, without stirring, for an hour and a half. When ready, add as much milk as may be wished, with a bit of butter, and let it just boil. Eat with sugar and a little curry-powder.

On the continent, in summer, thinner soups, such as the following ones, are much used:

Sour-milk Soup.—Take any quantity of sour-milk required, and boil with a few bits of lemon-peel and a little ground cinnamon. Prepare sufficient flour of rice with milk, to thicken it, and pour into the boiling sour-milk, stirring for a few minutes till ready. Sweeten with sugar or treacle, and add some grated almonds and raisins, according to taste.

Porridge Soup with Prunes.—Take a breakfast-cupful of oatmeal, and boil, with enough of water to make a soup, for an hour. A short time before serving, add treacle, vinegar, and cinnamon, according to taste.

Rice Soup.—Take a breakfast-cupful of whole rice, boil, with sufficient water, for an hour, and then add some ground cinnamon, and eight or ten drops of essence of lemon. It may be varied by boiling with the rice a few bits of lemon-peel, and by pouring the soup in the tureen on two or three eggs, beat up with a little sherry wine or rum, and stirring well. In this case, the butter is omitted.

Other soups of this kind are made with sago, potato-starch, &c., and flavoured with cranberry juice, raspberry vinegar, &c. The cranberries should be gathered at the proper season, and be preserved simply in water. In Norway, Denmark, &c., the juice is much used in soups, and the whole berries for tarts. They cost very little in these countries, and are frequently imported into this.

The Scotch working-man almost invariably takes his soup first, and eats afterwards a portion of the meat with which it has been made. When it is wished not to have the qualities of the meat too much diffused in the soup, it is sometimes taken out for an hour or so. Where mutton is used, instead of returning it to the soup, it may be sprinkled with a little pepper and salt, slightly browned before the fire, and served with an onion sauce, which is made by stewing a few onions in a little water for half an hour, and adding a little butter and flour. This greatly improves the qualities of the mutton. As has been already mentioned, when it is intended that the meat should be eaten without the soup, instead of using cold water, it should at once be immersed in boiling water, so as to coagulate the outer layer of albumen, and retain its juices; and then boil with closed cover very gently whatever time may be required, a quarter of an hour being allowed for each pound of meat. The water in which the meat has been boiled can be used next day as a stock for making broth or soup.

Roast Beef—for cooking which, see p. 759—is generally considered, in the working-man's house, an expensive dish; but when some kind of soup is used along with it, and account is taken of the dripping and bones, to be used in potato or pease soup, this may be doubted.

The following are good and economical forms of using beef, &c.:

Minced Collops.—Get a pound of steak minced very small, along with a bit of suet—in Scotland, the butcher usually does the mincing—put on in a stew-pan, with a good handful of flour, pepper, salt, and two tea-cupfuls of water. Have a wooden beater, and beat all the time they are cooking, to prevent lumps forming. They should be quickly made ready. As soon as they fairly boil all through, dish and serve them. Eat with vinegar and pickles.

Fried Beef-steak.—Take a pound of beef-steak, not too thickly cut, and beat well with the rolling-pin. Put a bit of dripping in the frying-pan, and brown the steak till ready with three or four sliced onions, and pepper and salt. When ready, put the steak and onions on the dish they are to be served on, and sprinkle a little flour in the pan, and brown it. Pour some cold water on this, with a little salt; bring to the boil, pour over the steak through a drainer, and serve hot.

Beef-olives.—Take a pound of beef-steak, and cut into three pieces, mince a little bit of suet with an onion or two; sprinkle this over the steak, with a little Jamaica pepper, black pepper, salt, and a little flour, and roll each piece up, and tie with a bit of thread. Put into a stew-pan, with a little water, a tea-spoonful of Jamaica pepper, a morsel of butter, a table-spoonful of flour, and stew slowly with closed cover for an hour and a half.

Beef à la Mode.—Take two or three pounds of hough or shin of beef; rub well with Jamaica pepper, black pepper, and salt; put on in a stew-pan with a very little water, a bit of fat bacon, a few sliced onions, carrot, and turnip; and stew very slowly with closed cover for four and a half hours. A quarter of an hour before serving, skim off the floating fat, and add a little browned flour and water.

Potato Pie.—Heat the oven, and make ready a panful of skinned potatoes. Put a pound of beef-steak into a pie-dish, with two or three sliced onions, pepper, salt, and a little water. Put a cover over this, and set it in the oven for half an hour. When the potatoes are ready, add a little milk and a bit of dripping, mash well, and cover the meat in the dish with them. If the oven is hot, the potatoes should be browned on the top and the meat ready in an hour. Before serving, add a small tea-cupful of hot water. Where there is not an oven, the Scotch 'girdle' may be used.

Beef-steak Dumpling.—Take a pound of beef-steak, and cut it into several pieces. Mix with one pound of flour a heaped tea-spoonful of Borwick's Baking-powder, add a quarter of a pound of lard, dripping, or minced suet, and make a paste with a small tea-cupful of water. Line a basin with this paste, and enclose the meat in thè dish with the same, adding three or four onions, pepper, and salt, and boil in a cloth for two and a half hours. While dishing, add a little hot water through a hole in the paste, and eat with potatoes. Mutton, veal, or lamb may also be similarly used.

Beef-steak, Pigeon, Crow, or *Veal Pie,* &c.—Take

three pounds beef-steak, beat it and roll in small pieces, previously sprinkling with Jamaica and black pepper, salt, and minced onions. Place in a pie-dish with some more sliced onions, pepper, and salt, and as much water as will fill the dish. Cover with a paste made as follows, which will also answer for tarts: Take a pound of flour, and mix with it a heaped tea-spoonful of Borwick's Baking-powder—a cheap article, which may be had at any druggist's—put in a bowl, and mix with this a quarter of a pound of lard, butter, or dripping, and rather more than half a tea-cupful of water. Stir round in the bowl with a spoon, and then roll over and over with the rolling-pin till smooth. Cut the paste out the size of the dish, roll out the parings, and cut them into strips. Wet the edges of the dish, and place these strips neatly round on the edges, as a foundation for the cover. Then, after putting in the meat, lay the cover on the dish, pressing down the edges closely to keep all tight. If any paste remain, cut or stamp it in ornaments—such as leaves—and place these as a decoration on the cover. Bake immediately in a hot oven for an hour and a half. Before serving, add a little boiling water for gravy.

Pigeon Pie is made in the same way, putting a pound of steak in the bottom of the dish, and seasoning only with black pepper and a very little onion. The pigeons must be cleaned well, a bit of butter rolled in pepper and salt put in each, and the gizzard, liver, and heart placed along with them.

Rook or *Crow Pie* is also made as above, putting a piece of fat bacon in each, and in the bottom of the dish, instead of the steak. The rooks—which should be young birds—have to be skinned, and care must be taken not to burst the gall-bladder in gutting them.

Veal Pie is made in the same way, with bacon, the seasonings being white pepper, salt, parsley, a little bit of onion, and a slice of lemon, keeping out the seeds of the latter and the end portions of the rind. *Chicken Pie* is made with the same seasonings.

Irish Stew.—Take a pound of neck of mutton, cut into small pieces, and brown with dripping in the frying-pan. Put into a stew-pan, with as much water as will cover the meat, plenty of onions, black pepper, and salt. While it is stewing slowly with closed cover, skin and slice as many potatoes as may be wanted, and place them over the meat. Close the cover, and stew for two hours very slowly, so as not to let the potatoes burn.

Stewed Veal.—Take two pounds of any fleshy part of veal, and cut into neat pieces. Have an egg beat up, and some bread-crumbs, with minced parsley, onions, white pepper, and salt, on a plate. Have some lard or dripping in the frying-pan. Dip the cut veal in the egg, and then in the crumbs, and fry till the veal is of a nice light brown. Put in a stew-pan with a little water, two tea-spoonfuls of flour, an onion, a little parsley, and two slices of lemon, and stew slowly with closed cover for an hour. Serve with some slices of lemon round the dish.

Curried Rabbit, &c.—Cut a rabbit into pieces, wash well, and put in a stew-pan with a quarter of a pound of butter, a dessert-spoonful of curry-powder, and three or four large onions, and as much water as will cover the meat. Stew slowly with closed cover for two hours. Half an hour before dishing, add a table-spoonful of flour moistened with cold water. Eat with potatoes, and rice prepared as follows: Take a breakfast-cupful of rice, wash till the water runs clear, and put on with just as much water as will cover it, adding a little salt. Let it simmer very slowly with closed cover, without stirring it, for an hour and a quarter. It should be quite dry when dished. Excellent curries may be made in the same way by using fowl or chicken, fish, ox-heart, or any cold meat. The fish and cold meat will be ready in half an hour; the ox-heart ought first to be parboiled, and requires two hours to make it ready. If the curry-powder is omitted, these dishes are all stews.

Salt Fish.—Cut the salt cod or ling into pieces, and soak in plenty of water for thirty-six hours. Put on in plenty of cold water, and let it simmer slowly with closed cover for three hours. Make a sauce of butter, flour, and water, with one or more hard-boiled eggs minced into it, and eat with mustard and potatoes. If there is any fish left, bone it next day, mix up with beat potatoes and a good bit of butter, and brown before the fire.

Oatmeal Pudding.—Take a pound of suet, mince with it six onions, and add this to a pound and a half of Scotch oatmeal, with pepper and a very little salt. Boil for three hours, and eat with potatoes. A little bit of parboiled liver, minced with bacon, may be added if wished.

White-skin Pudding.—The same ingredients, without the liver and bacon, may be used for making white-skin puddings. The small intestines of the ox or sheep are used, and must be particularly well cleaned, and not stuffed too full. They should be boiled very gently for half an hour, and hung up for use. Parboil and toast before the fire before eating.

Black Puddings.—Mince two pounds of suet, twelve onions, pepper, salt, and a little sage dried and rubbed into powder, and stir together with two handfuls of oatmeal and three imperial pints of ox's or pig's blood. Fill the skins as above, and boil slowly for half an hour. Hang up, and use as before.

Fried Liver.—Take a part of the portion called the 'tongue' of an ox's liver, parboil, cut into thin slices, and fry with sliced onions and fat bacon. Remove the liver and bacon, sprinkle a little flour in the pan, and brown it; pour on a little water, and bring to the boil as sauce. Lamb or sheep's liver should be cut in thin slices, but does not require to be parboiled.

Dressed Sheep's Pluck.—The pluck in Scotland includes the heart, lungs, and liver. Take a sheep's heart, lungs, and half of the liver, and parboil. Mince fine with two or three onions, parsley, pepper, and salt. Put in a stew-pan with a handful of flour and two tea-cupfuls of water. Stew slowly with closed cover for an hour and a half. Cut the other half of the liver into thin slices, fry with fat bacon, and serve round the stew.

Mutton Haricot.—Take a pound of mutton-chops, beat, and brown in the frying-pan with lard or dripping. When browned, put in a stew-pan, with just as much water as will cover the meat, pepper, salt, a sliced carrot, a turnip, and two or three onions. Stew slowly for an hour and a half, adding a dessert-spoonful of flour, moistened with a little water, a quarter of an hour before serving. These dishes, however well cooked, will yet lose half their relish if served in a slovenly manner, or allowed to get cold and out of season. Where the meats are hot, they should always be dished and served quickly, and especially always be eaten from heated plates.

From the directions which are to be found under their proper heads, the housewife will have no difficulty in now and then making nice additions to her dinner fare in the form of a pudding, a dumpling, or a tart. These, when properly managed, are wholesome dishes, and, where fruit is cheap, are not very expensive. For the tarts and pies, however, it is quite essential that the housewife have a good working oven; and we have shewn that there is no great difficulty in obtaining this. The materials for tarts most accessible are—in spring, the Victoria rhubarb, and, as the season advances, this mixed with gooseberries, or gooseberries alone. When the rhubarb has become old, it is generally little used, and is cheap. When, however, at this season it is mixed with blaeberries, or wild rasps, it makes a delicious tart. Currants, apples, and other fruits can be used when convenient. The wild rasp makes a delightful preserve for using in dumplings, and for eating with boiled rice and cream, or milk, &c. For

this purpose, making this and red gooseberry jam should be attended to at the proper season. Directions for making these will be found at page 765.

A very plain dinner is made delicious where there are plenty of tender, well-dressed vegetables, of which an abundance may easily be obtained where a workman possesses a little garden. Where he has done justice to his garden, and has applied liquid manure, guano, &c., thus causing the plants to rush quickly up, the commonest vegetable becomes a treat; for example, cabbages—often a coarse vegetable—either alone or beat up with potatoes and dripping, makes a delightful relish. During the summer, too, a small morsel of ground will give him the means of having a constant supply of delicious salads. He has only to tie with a bit of string the tops of his lettuces, and thus blanch them, and to mince them with young onions and a hard-boiled egg, mixing with vinegar and salt, to have, through the warm season, a salad which even a gourmand would not despise; while his young cresses and radishes form a relish for breakfast, dinner, tea, or supper.

Having spoken, as fully as our space will allow, of the more solid dishes a workman may command, we have only a few words to say as to some other matters. For *tea*, he can have, as a variety to his bread and butter, cakes of various kinds. *Soda scones*—done in the oven, or on the 'girdle' used in Scotland—are made by mixing with the flour a little carbonate of soda, salt, and churned milk, rather sour. If the milk should not be sufficiently sour, a little tartaric acid may be added, to quicken the effervescence from the soda. They can be made richer by adding a little lard or dripping. A very nice kind of domestic *crumpet* is made with the same materials, mixed just thin enough to pour, the girdle being previously made hot, and greased with lard. They are rather difficult to turn; but by loosening the edges, and using a broad knife, this can easily be managed with a little practice. They should be eaten hot with salt-butter. *Scotch oat-cakes* are eaten with relish, when well made, by all classes. Their excellence chiefly depends on their being short and crisp, which qualities are procured by adding to the water with which they are made, that little carbonate of soda, and firing them slowly, so as they shall be thoroughly done; and when a few days old, they should be again slightly heated, to bring back their crispness. When they are wanted richer and very crisp, a little lard or lamb-dripping may be used, and the soda omitted.

For *supper*, a bit of cheese, a little porridge, a salad, a hard-boiled egg with pickles, milk in some form, &c., will be taken according to taste.

Curried Milk.—In cold weather, a wholesome and very palatable form of using milk is as follows: Boil the milk, and add a little salt, sugar, and curry-powder. Use this with bread cut thin and toasted hard, cut in small pieces.

Pease Brose is a favourite supper with some in Scotland. It is made with the Glasgow brose-meal as follows: Put as much meal as is required in a bowl, with a little salt, and stir boiling water into it, making it of a thick consistency. Eat with sweet or butter milk.

Killing a pig gives the means, to a cottager's or workman's family, of having several nice luxuries, such as the blood and white puddings, the dressed 'pluck,' the salted 'pig's cheek,' eaten with greens, the feet salted slightly, and made into delicate soup with vegetables, tasty pork-sausages, rich pork and mince pie, and delicious spare-rib roasted. The suet should be carefully 'rinded' by melting off the lard in a pot placed in boiling water, adding a little salt, and then should be put in pots covered with bladder, or in bladders, to exclude the air. It may be used, when required for pie-crust, &c.

Pork Sausages are made by mincing the fat and lean pork, seasoning with black and Jamaica ground pepper, dry sage rubbed down, and half filling the intestines —well cleaned—and frying.

The *Spare-rib* is a favourite part of the pork for roasting in England. A good bit of the lean meat is left on when the flesh is cut away. This mode of cutting should be adopted in Scotland.

Pork Pies are much made in England, and are greatly relished when eaten cold. Take any spare pieces of pork, mixed lean and fat, cut into small pieces, and flavour with dried sage, rubbed down—a little ground mace is sometimes added—black and Cayenne pepper, and salt. Enclose in a paste, as described under head 'Beef-steak Pie,' of the same shape as the small mutton pies, but of any size wished; add a little water, bake in a not too hot oven for two hours or so, according to size, and eat when cold. The same meat, &c., can be made into a dumpling, as described under head 'Beef-steak Dumpling,' and eaten hot.

ROASTING.

Meat is roasted by being exposed to the direct influence of fire. This is done by placing the meat before a fire, and keeping it constantly in motion, to prevent scorching on any particular part.

Dripping.—Roast-beef yields a dripping, which is a valuable article in the economy of the kitchen. It should be removed from the pan beneath the meat before it becomes overheated, or scorched by the fire, leaving sufficient for basting. Dripping is prepared for future use in the following manner: Take it hot from the dripping-pan and pour it into boiling water, that all particles of cinder or other improper matter may fall to the bottom, and leave the pure fat on the surface. Collect these cakes of fat, and by heating them in a jar, placed in a sauce-pan of boiling water, the whole will become a solid mass, and may be thus put aside for use. This process not only purifies dripping, but gives it a clear white colour.

To roast Beef.—The best piece of beef for roasting is the sirloin. If the suet be not required, it may be ordered to be cut off before purchasing the joint; a small piece of suet is all that is requisite for the purpose of basting. If at all musty, it should be washed with salt and water, and wiped quite dry. Hang it on the hook of the jack, in the way most advantageous for being operated upon uniformly by the fire. Handle it as little as possible. The fire must be quite clear and brisk. It is customary to allow a quarter of an hour for every pound of the meat. While roasting, baste it very frequently with its own dripping. In dishing, pour a little boiling water and salt over it for a gravy. A well-roasted joint ought to have a nice rich brown tinge, and this is to be obtained only by careful basting, attention to the fire, and removing at the proper time, when experience tells that the joint is 'done.' Garnish with scraped horse-radish.

To roast Mutton.—The best parts of mutton for roasting are the leg, the shoulder, and the loin. The piece may be kept longer than would be desirable for mutton for boiling. It should have a clear and brisk fire. A leg will take two hours to roast; but this, as well as the time for roasting the other parts, must be regulated by the fire and the weight of the meat, and can be learned only by attention. The joint of mutton should be basted the same as beef, with its own dripping, and a gravy should be made for it as above.

To roast Venison.—Venison is roasted in the same manner as mutton, but requires longer time at the fire. It is such a dry meat, and the fat is so easily melted, that it should be covered with buttered paper, and well basted. Serve with a good gravy and currant-jelly.

To roast Veal.—The best parts of veal for roasting are the fillet, the breast, the loin, and the shoulder. The fillet and the breast should be stuffed, particularly

the fillet, with a composition of crumbs of bread, chopped suet and parsley, a little lemon-peel, and pepper and salt, wet with an egg and a little milk. Let it be well basted with butter when there is not sufficient dripping from the joint. The gravy for roast veal is either the usual hot water and salt, or thin melted butter, poured over the meat.

To roast Lamb.—Lamb also requires to be well roasted. It is usually dressed in quarters; all parts, particularly the spinal bone, should be well jointed or cut by the butcher or cook; and the ribs of the fore-quarter broken across the centre, in order to accommodate the carver. In roasting, baste, as already described, with its own dripping. The gravy for lamb may be the same as for beef or mutton—namely, hot water and salt poured over it. A very nice stuffing for lamb is often used in Scotland: mince some of the suet, an onion, and a few blades of parsley, and mix with a handful of oatmeal, a little pepper, and a very little salt. Make a hole in the loose skin of the loin, fill with the above, and sew up. Eat with the lamb, and mint-sauce.

To roast Pork.—Pork requires a longer time in roasting than any of the preceding meats. When stuffing is to be used, it must be composed of chopped sage and onion, pepper and salt. The pieces should be neatly and well scored in regular stripes on the outer skin, to enable the carver to cut slices easily. Before putting to the fire, rub the skin with salad-oil, to prevent its blistering, and baste very frequently. The basting may be done by rubbing it with a piece of butter in a muslin bag, where there is not enough of dripping. The gravy for pork may be the same as for other joints, hot water and salt poured over it on the dish. It is considered an improvement to have apple-sauce served in a small tureen, as it assists in overcoming the richness or lusciousness of the meat, and imparts an agreeable acidulous flavour.

To roast Bullock's Heart.—Wash the heart well, freeing it completely from blood. Then fill all the openings at the top or broad end with a stuffing composed of crumbs of bread, chopped suet, parsley, pepper and salt, moistened with an egg and a little milk. Suspend with the pointed end downwards. An hour and a half, or two hours, according to the degree of heat, will cook the dish. It should, however, be well done. Send to table with beef-gravy.

To roast Fowls.—Pick, draw, and singe them. A fowl should be so cleanly or well drawn as to require no washing. Take care not to break the gall-bag in drawing; if the gall be spilled, it will communicate a bitter taste to every part it touches. Press down the breast-bone. Break the legs by the middle of the first joint, drawing out the sinews, and cutting off the parts at the break. It being proper that roast fowls should have a neat appearance at table, it is customary to *truss* them—that is, to fix their legs and wings in a particular position. This is done by fixing down the knees of the animal close to the tail by a skewer or piece of string, leaving the stumps of the legs projecting. The pinion ends of the wings are then turned round on the back, the liver being placed as an ornament in one wing, and the gizzard in the other. Cut the head off close to the body, leaving a sufficiency of the skin to be tied or skewered on the back. Baste well with butter for some time after putting to the fire. Suspend neck downwards. The time of roasting will vary from half an hour to an hour, according to the size of the chicken or fowl. When a fowl is large, it is frequently stuffed like a turkey. Serve roast fowls with melted butter or a sauce made of the neck, the liver chopped, a little butter and flour. Before sending to table, remove all skewers and strings which may have been used in trussing. This, which should be done in all cases of serving dishes to table, is too frequently neglected, and shews slovenliness in cookery. Fowls, and all other feathered animals, are served with the breast upwards.

To roast Turkey.—Pick, draw, and singe the turkey well. Press down the breast-bone, and follow all the directions given for trussing fowls. The breast should be stuffed with crumbs of bread, minced beef-suet or marrow, minced parsley, a little nutmeg, pepper, and salt; wet it with milk and egg; a little sausage-meat may also be added. On finishing, sew up the orifice or neck. Before putting to the fire, cover the breast with a sheet of writing-paper well buttered, to preserve it from scorching, and which may be removed a short time before taking from the fire, to allow the breast to be browned. Baste well with butter. A turkey will take from an hour and a half to two hours. Serve with gravy-sauce.

To roast Pigeons.—Pick and draw them well, and truss, keeping on the feet. Make a stuffing of the liver chopped, crumbs of bread, minced parsley, pepper, salt, and a little butter; put this inside. Make a slit in one of the legs, and slip the other leg through it. Skewer and roast them for half an hour, basting them well with butter. Serve with beef-gravy in a small tureen, and on toast-bread placed under them while roasting, to catch 'the trail.'

To roast Partridges and other Game.—Pick, draw, singe, and clean these birds the same as fowls. Leave the head on, make a slit in the neck, and draw out the craw. Twist the neck round the wing, and bring the head round to the side of the breast. The legs and wings may be trussed in much the same manner as fowls. The feet are left on, and crossed over one into the other, as seen in the annexed figure. Baste well with butter before a clear fire. When about half done, dust a little flour over them to be browned. A partridge will take from twenty minutes to half an hour, and a pheasant three-quarters of an hour. Serve on toasted bread, with gravy, as above. Grouse and black-cock should be dressed and served in the same manner; the head being trussed under the wing. Snipes and woodcocks are not drawn.

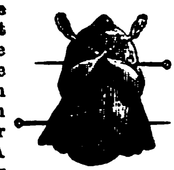

Fig. 3.

To roast Goose.—Pick, draw, and singe the goose well. Cut off its head and neck. Take off the legs and wings at the first joint. The portions of the legs and wings that are left are skewered to the sides. Stuff with chopped sage and onion, and crumbs of bread, with pepper and salt. The skin of the neck must be tied securely, to prevent the gravy from running out. Paper the breast for a short time. A goose does not require so much basting as fowl or turkey, for it is naturally greasy. It will require from two hours to two hours and a half in roasting. It ought to be thoroughly done. Serve with gravy-sauce and apple-sauce. The liver, gizzard, head, neck, feet, scalded and skinned, and the pinions of the goose, form what is termed the *giblets*, and compose a good stew or pie. The blood of the goose makes a good blood-pudding, using bread-crumbs instead of oatmeal, as directed, p. 758. It can be done before the fire, or in the oven. Sometimes it is included in the skin of the neck cut off, and tied at both ends, and is baked in the giblet-pie.

To roast Ducks.—Pick, draw, and singe them well. Take off their heads. Dip their feet in boiling water, to take off the outer yellow skin. Truss them neatly, turning the feet flat upon the back. Stuff as in the case of goose, and serve with the same sauces. A duck requires about an hour in roasting.

To roast Hare.—A hare will keep with the skin on it, and paunched, for two or three weeks in cold weather. It is then fit for roasting. First cut off the feet, and commence drawing off the skin at the hind-legs, proceeding along the body to the head. Be careful not to tear the ears in skinning them. Soak and wash well in several waters, and then wipe quite dry. Stuff with

crumbs of bread, chopped parsley, a bit of beef or veal suet chopped finely, a little grated lemon-peel and nutmeg, a piece of liver boiled and finely chopped or grated, and pepper and salt; the whole moistened with an egg,

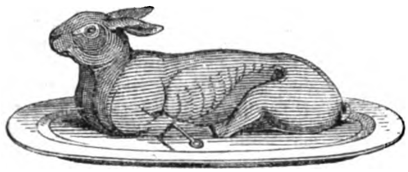

Fig. 4.

a little milk, and a spoonful of ketchup. The skin of the belly afterwards to be sewed. Commence trussing, by placing the hind and fore legs flat against the sides. To make the hind legs lie flat, the under sinews must be cut. Fix the head between the two shoulders, on the back, by running a skewer through it into the body. In roasting, suspend head downwards. It should be basted first with milk, afterwards with butter, flouring it lightly. It will require from an hour and a half to two hours. The hare is dished back upwards, as represented above, and served with a dish of rich beef-gravy, and a dish of currant-jelly.

BAKING.

Meat is prepared for baking in the same manner as for roasting. It should be placed in a deep dish for receiving the fat which flows from it; not laid, however, on the sole of the dish, but raised on a stand, to prevent the grease soaking into it. Small iron stands are made and sold for this purpose. Few dishes are so good when baked as when roasted, the meat being so liable to be shrivelled for lack of basting; and being liable, moreover, if done in a baker's oven, to partake of the flavour of the multifarious articles which are there prepared. Perhaps the only dishes which are better baked than roasted, are bullock's heart and leg of pork, because in roasting they are liable to be scorched on the outside before they are thoroughly cooked in the inner parts. In baking a heart, place it in a stand in a dish with the point downwards; a piece of writing-paper, buttered, may be placed over it, to keep the stuffing from drying. The sauce used is beef-gravy.

BROILING.

Broiling is the rapid cooking of any kind of animal food by the influence of fire. The apparatus required in broiling is very simple, and consists only of a gridiron, whose bars should be small bars, and kept thoroughly clean, not only on the tops, but on the sides. An improved form of gridiron consists of channeled bars leading to a trough or receptacle for the exuded juices. Let the iron be heated for a few minutes before placing the meat upon it; and rub the warm bars with a piece of brown paper, to prevent the meat from sticking to them. The operation of broiling requires a clear strong fire, with no smoke. In almost all cases, the meat ought to be frequently turned, which may be best done by a pair of small tongs; a fork should on no account be used in turning, for it breaks the skin of the meat, and allows the gravy to run out. Broiling possesses the peculiarity of being applicable only to meat which is to be eaten immediately on being dressed. This is an advantage when expeditious cooking is required, but a disadvantage when there is any uncertainty as to the time at which the meat is to be eaten. It is by no means an economical method, as a great proportion of the nutritious juices is discharged from the flesh beyond the means of recovery.

To broil Beef-steak.—A beef-steak is the most suitable of all kinds of meat for broiling, and is a dish universally relished. There are several parts of beef used for steaks, but in no case should it be from an animal too newly killed. The best steak is that cut from the rump—called in Scotland the *heuk-bone*—because it is the most juicy and well flavoured. Steaks should be cut in slices of from three-quarters of an inch to an inch in thickness, and into pieces of a convenient size for turning. Some persons dust the steaks with pepper before putting them to the fire, by which means the flavour of the pepper is infused through the mass. When placed on the gridiron, turn them very frequently; it is said, indeed, that the steaks should never be at rest, but this is carrying matters to an extremity. It is impossible to state any exact length of time to be employed in cooking a steak, for much depends on the tenderness and thickness of the meat, and the strength of the fire. The taste of the individual who is to eat the steak must also regulate the length of time; because, while some prefer steaks in a half-raw state, others wish them to be well done, that is, to have the colouring matter of the blood fully coagulated. When cooked to the extent which is required, place the steak on a hot dish, and after rubbing it with a little good fresh butter, sprinkle it with a little fine salt. Beef-steaks should be carried to table immediately on being dressed, and eaten forthwith, in order to be in perfection. Every moment they stand, they lose a portion of their flavour and juice. When sauce is required, either ketchup or oyster sauce may be used.

To broil Mutton-chops.—Mutton-chops should be cut from the middle of the hind loin, and about the same thickness as steaks. They are broiled in the same manner as steaks, and require equal attention. No butter is to be used on dishing, as the chop is sufficiently fat of itself. Sprinkle a little salt on it, and carry to the table immediately. Ketchup may be used as an adjunct.

FRYING.

Frying is as expeditious a mode of cooking as broiling, requires less activity and care, and is more thrifty. The thriftiness of frying is a point of material consequence, and may be thus explained. It affords a ready means of dressing in a savoury manner many odd pieces of uncooked or cold meat, thereby saving that which might otherwise have been thrown away as useless. A skilful housewife, with the aid of a frying-pan and some cheap vegetables, such as onions and potatoes, along with a slight seasoning, will make a small portion of meat dine a large family. A frying-pan should be of malleable, not of cast iron. It should also be thick in the bottom, and of an oval form. It should always be kept clean, by being washed with boiling water, but not scoured. In using it, a small piece of dripping, butter, or lard, must be put into it, and melted, to prevent the meat from adhering to it. In frying all meats, excepting those which are sufficiently fat in themselves, it is necessary to use some kind of grease or fat. The best fat for this purpose is lard, which is more economical, and less likely to get burned than butter. When lard is not employed, the best substitute for it is dripping.

To fry Mutton-chops.—They require to be cut in the same manner as for broiling, and may be dressed according to the directions for steaks, &c. None of the grease which flows from the chops is to be used along with them, and the whole must be poured away before preparing the gravy.

To fry Veal Cutlets.—Veal cutlets form a delicate dish, and should be fried with butter. The best cutlets are from the fillet, because they are free from bone; the fore or hind loin—that is, the back-ribs or loin—may be used, but the bone must be cut away, which causes a waste. Cut them half an inch in thickness. They require to be dressed slowly and thoroughly, and should be of a light-brown tinge when finished.—Another and more tasteful way of dressing cutlets, is to dip

them in a beat egg, strew them with crumbs of bread, and parsley chopped very fine, along with pepper and salt, and then put them in the pan. They will require more lard or dripping this way than when fried plain. Gravy may be made for cutlets the same as for fried steaks, but add a little juice of a lemon, and skim the gravy before pouring it over the cutlets. Serve with slices of lemon.

To fry Lamb-chops.—Lamb-chops may be either simply fried in the same manner as mutton-chops, or dressed with egg and crumbs of bread (but with no parsley), as in the case of cutlets. Gravy made in the pan, as for fried steaks.

To fry Pork-chops.—Pork-chops should be cut rather thin, and be thoroughly dressed. They may be either simply fried in the same manner as chops, or fried after being dipped in egg, and sprinkled with crumbs of bread, and sage and onion finely chopped. No gravy is expected with pork-chops. If any sauce be used, it must be apple-sauce.

To fry Beef or Pork Sausages.—All sausages are fried alike, and require to be dressed very slowly. Before being put into the pan, they should be pricked in several places with a fine fork, to prevent their bursting by the expansion of the air within. It is common in England to bring fried sausages to table neatly laid out on a flat dish of mashed potatoes. The sausages and potatoes are helped together. They may also be laid in links on toasted bread, and garnished with poached eggs round the dish. Fried sausages are sometimes used for garnishing roast turkey.

To fry Tripe.—The tripe must be washed well, and boiled till tender. Take the thickest parts, and dry them well with a cloth. Make a thick batter of egg, flour, and milk, seasoned with salt, and for those who wish it, a little minced onion. Dip the tripe into the batter so formed, after which fry in lard or good fresh dripping, of which there must be a sufficiency in the pan almost to cover the tripe. Let it be done to a light-brown. Garnish with fried parsley.

To fry Bacon, or Ham and Eggs.—The bacon should be cut in slices about an eighth of an inch in thickness. The best bacon is that which is alternately streaked with fat and lean. No butter or dripping is required in the pan in frying bacon, which does not need much dressing, and is soon prepared. When done, take the slices from the pan, and place them in a hot dish before the fire. Have the number of eggs required previously broken, each in a separate cup, and place them gently in the pan, so as to preserve them in a round flat shape. Let them remain in the pan till the white is set, and take them out carefully with a slice, and place them on the bacon. The tasteful appearance of this dish is spoiled if the eggs be either broken or ragged, which is very apt to be the case if they are not previously put into cups.

BOILING.

Boiling is the preparation of meat in water, and it is necessary that the vessel employed be large enough to allow the meat perfect freedom; if it be cramped, and have only a little water, it will be stewed, not boiled. In all cases of boiling, there must be a sufficiency of water to cover the meat. In boiling meat, there is less waste than in roasting; and in most cases, soup may be made of the liquor. As has already been remarked, the general direction to be attended to in boiling meat is, that where soup is to be made, the meat must be put into *cold* water, and very gently boiled; but when the chief object is to get the meat for eating, it is at once to be immersed in *boiling* water, and also very gently boiled—in both cases, with a closed cover.

When meat of any kind is done, and has to be lifted from the pot, take care not to put a fork into any part where there are juices; if this be not attended to, a portion of the juices will escape, and the marks of the fork will produce an unsightly appearance in the meat. All parts of mutton and lamb may be roasted, but it is only the leg, neck, and head that are boiled.

To boil a salted Round of Beef.—If large, cut out the bone, roll it up firmly, and bind it with a tape; then put it into the pot, and keep the lid close. Boil it slowly and equally, allowing a quarter of an hour for each pound of the beef. The appropriate garnishing for this and other pieces of boiled salt beef, is carrot and small greens; some add turnips. Put a little of the liquor in which it has been boiled in the dish.

To boil a Leg of Mutton.—A leg of mutton should be kept four or five days before boiling. Before putting it into the pot, bend round the shank, cutting the tendon at the joint, if necessary, so as to shorten the leg. Two hours of slow equal boiling will be sufficient for a good-sized leg of mutton. Some persons, to make the leg look white and tasteful, wrap it tightly in a cloth in boiling; but this spoils the liquor for broth. It is not safe to boil vegetables with a leg of mutton, as they are apt to flavour the meat. Dish the leg with a little of the liquor, placing the lower side uppermost, conveniently for carving. A good leg of mutton will soon yield sufficient gravy. For sauce, use finely chopped capers in melted butter, or the latter with pickled walnuts. Turnips mashed or whole form the appropriate vegetable to be eaten with this dish.

To boil Veal.—Veal is seldom boiled, being too insipid by that mode of dressing. The only part boiled is the knuckle, which requires much boiling, in order to soften the sinews. It is eaten with boiled ham or bacon. The sauce used is parsley and butter. The liquor from veal is the best of any for making soup.

To boil a Turkey.—Boiled turkey is one of the most delicate and excellent dishes which can be brought to table, and should be dressed with as much care as possible. Clean the turkey from all feathers, and singe the hair with burning paper, being careful not to blacken the skin. Clean it well inside by drawing and wiping. Cut off the legs at the first joints, and draw out the sinews; then pull down the skin, and push the legs inside. Cut off the head close to the body, leaving the skin long, and draw out the craw. Make a stuffing of chopped suet, crumbs of bread, chopped parsley, pepper, salt, and a little nutmeg, which wet with an egg and milk. Put this stuffing into the breast, leaving room for the stuffing to swell; after which draw the skin of the breast over the opening, and sew it neatly across the back; by which means, when the turkey is brought to table with its breast uppermost, no sewing will be seen. Place the liver in one wing, and the gizzard in the other, turning the wing on the back, and fixing the wings to the sides with a skewer. The turkey being now ready for the pot, put it into a cloth, and boil it for a length of time according to the size and age. A small young turkey will not require more than an hour and a half; an old and larger one, perhaps two and a half or three hours. Let the water be boiling in putting in, and of sufficient quantity to keep the turkey always covered. When done, and placed in a hot dish, pour a little sauce over the breast, and put the remainder in a sauce tureen. The sauce used is various—as parsley and butter, celery, or oyster sauce. One of the most delicate and agreeable sauces is that which is made of melted butter, boiled macaroni, and milk.

To boil a Fowl.—A fowl is to be prepared for boiling in the same manner as a turkey, except that no stuffing is used. It may be boiled with or without a cloth. Small fowls will require from half an hour to three-quarters of an hour; large fowls will require from an hour to an hour and a half. Sauce, parsley and butter.

To boil Rabbits whole.—Wash them well in warm water. They may be either stuffed or not stuffed, according to taste. When stuffing is required, make it of crumbs of bread, suet, parsley, and onions—all chopped—and pepper and salt; moisten with milk and

egg. Sew this neatly into the belly. Truss in the same manner as roast hare, and boil slowly for an hour. The sauce to be made of boiled onions, milk, melted butter, and flour, with pepper and salt, which pour over the rabbits when dished. This is called *rabbits smothered in onions.* When two rabbits are dished together, always lay the head of one in a contrary direction to that of the other.

To boil a Ham.—If the ham has been cured long, it may require soaking in cold water to soften it, from twelve to twenty-four hours before dressing. Put it in a large boiling vessel, with plenty of cold water, and let it simmer slowly from two to four hours, according to the size. Skim it frequently, to remove the grease which is constantly rising to the top. When done, skin it, and strew bread-raspings over the upper side; then place it before the fire to dry and brown. Garnish with greens or cabbage.

To boil Leg of Pork.—Pork requires to be particularly well boiled. Place it in the pot with the skin-side uppermost, with a plate below it, for pork is very apt to stick to the bottom of the pot. Pease-pudding is generally served separately with this dish.

To boil a Tongue.—If hard, soak the tongue in water all night before using. Boil it from two hours and a half to three hours. Skin it before dishing. Garnish with greens or spinage.

To boil Tripe.—When tripe is purchased from the butcher in a raw state, it requires to be boiled a very long time, to be thoroughly soft and tender. The length of time will depend on the age of the animal from which it has been taken. Sometimes, for young tripe, six or seven hours will be sufficient, while old tripe will perhaps take ten or twelve. In all cases, boil, or rather simmer it very slowly, for quick boiling hardens it. It should be cut into moderately sized pieces for helping at table. When to be served plain, carry to table in a hash-dish, in some of the water with which it has been boiled, with boiled onions in it. A tasteful way of serving is to take it from its liquor after boiling, and stew it for about ten minutes in a sauce-pan with milk, which thicken with a little arrow-root, or flour and butter, and season with pepper and salt, immediately before dishing, as otherwise the salt is apt to curdle the milk. This makes a delicious and cheap dish.

To boil Cow-heel.—Cow-heel should be boiled for five or six hours, or till the bones will slip out. Serve with a sauce of chopped parsley and butter.

To boil Eggs.—The boiling of eggs is a very simple operation, but is frequently ill performed. Put the egg gently into a pan of hot water just off the boil, and boil for three minutes or more, if the egg be quite fresh; or two minutes and a half, if the egg has been kept any time.

STEWS, HASHES, AND MADE DISHES.

Stewing is the preparing of meat by slow simmering or boiling, all the liquor being used along with the meat at table. This is a much more savoury and nutritious mode of cookery than boiling, because the substance of the meat is partly in the liquor, and is seasoned to have a high relish or flavour. Generally, much more can be made of meat by stewing than by roasting, boiling, or frying, because nothing is lost in the process of dressing. It also possesses the decided advantage of being a way by which meat may be dressed for a person whose time of dining is uncertain. A stewed steak, for instance, will keep warm and in good condition for an hour, but a broiled or fried steak cannot keep a minute after dressing.

To stew a Piece of Beef, or make Beef Bouilli.—Take a piece of beef—the brisket or rump, or any other piece that will become tender. Put a little butter in the bottom of the stew-pan, and then putting in the meat, partially fry or brown it all over. Then take it out, and lay two or three skewers in the bottom of the pan; after which replace the meat, which will be prevented from sticking to the pan by means of the skewers. Next, put in as much water as will half cover the meat. Stew it slowly, with the pan closely covered, till done, with a few onions if required. Two hours are considered enough for a piece of six or eight pounds. When ready, take out the meat, and thicken the gravy with a little butter and flour. Cut down into handsome shapes a boiled carrot and turnip, and add them to the liquor; season with pepper, salt, and ketchup. Boil all together for a few minutes, and serve in a hash-dish.

To dress Cold Boiled Beef, or make Bubble and Squeak.—Cut the beef in slices of about the third of an inch in thickness. Fry the slices till lightly browned and heated through. Then take them from the pan, and place them on a warm plate before the fire, to keep hot. Fry some cabbage which has been previously boiled and chopped; stir this about a short time in the pan, and season with pepper and salt. Spread the cabbage in a dish, and place the slices of meat upon it; or heap the cabbage in the dish, and place the meat around it.

To mince Cold Veal.—Cut the veal from the bones, and mince it in small square bits, and lay them aside. Then put the bones in a stew-pan with a little warm water, to make a gravy. After stewing for a short time, take out the bones and put in the bits of veal, with a small piece of lemon-peel, chopped very fine. When perfectly heated, thicken with a little flour and butter, and season with pepper and salt, and a little lemon-juice. Dish with small pieces of toasted bread, placed round the edge of the dish.

To dress a Lamb's Head and Pluck.—Lambs' heads are procured skinned. Take the head with the neck attached; split up the forehead, and take out the brains, which lay aside. Wash the head carefully, cleaning out the slime from the nose by rubbing it with salt, and take out the eyes. The head being thus cleaned, put it on to boil, along with the heart, and the lungs or lights. Let the whole boil for an hour and a quarter; then take them out, and dry the head and neck with a cloth. Rub it over with an egg well beaten; strew crumbs of bread, pepper, and salt over it; also stick small pieces of butter over it, and lay it in a dish before a clear fire, to be browned lightly. Mince the lungs and heart, and part of the liver, with some onion, parsley, pepper, salt, a little flour, and a table-spoonful of ketchup; mix all together, and add some of the liquor in which the head was boiled to form a gravy; let it simmer by the side of the fire for half an hour. Take the brains and beat them well with two eggs, two table-spoonfuls of flour, and a sprig of fine chopped parsley, also a little pepper and salt, and two or three table-spoonfuls of milk—the whole forming a batter. Have a frying-pan with a little lard or dripping, and fry the batter in small round cakes, which turn and brown lightly on both sides. Cut the remainder of the liver in slices, and dust it with flour, and fry it. Now lay the head upon a dish; place the hash round it, and lay a slice of liver and a brain-cake alternately on the hash all round. This forms a handsome and a savoury dish, but requires great attention on the part of the cook, to have all the various parts hot and equally ready at the time of dishing.

To make Potted-head.—This is a dish to be eaten cold as a jelly. Take the half of a bullock's head, and clean it; soak it in warm water, with a cow-heel, for two or three hours. Then boil very slowly with closed cover for eight or ten hours. When done, cut them in small pieces, and lay them aside; after which strain the liquor in which they have been boiled, and let it stand till it is cold, so that the fat may be easily skimmed. Put the whole into a sauce-pan, and boil for half an hour, and season with pepper and salt according to taste. Pour it into basins, or tin or earthenware shapes, which stand in a cool place. When quite cold, it forms a

jelly, and is ready for being turned out on a dish for use. If it do not come out easily, dip the basin or shape in hot water, and the heat will immediately loosen it. Garnish with sprigs of fresh parsley.

Potted-beef.—Take a hough or shin of beef, cut in pieces, and put in a brown can, and fully cover with water. Put a plate over the can, and closely tie down with paper, and stew gently all night by the side of the fire, or in a cool oven. In the morning, pour off the liquid into a brown plate, cut up the pieces of meat, and pound well in a mortar with black pepper, salt, and a little ground mace, Jamaica pepper, or cloves. Take a little of the gravy from under the fat, and mix well with the pounded beef. Put in jelly-cans or small pie-dishes, and place in the oven or on the girdle, and bring gently to the boil. Set aside until cool, and then run over the top of each a little butter melted, or a little of the fat from the beef—the first is the better—to exclude the air. Set aside in a cool place, where it may be kept fresh for months. Remove the fat from the remaining gravy, and use for pie-crusts, &c. The gravy itself can be used as an excellent stock for any soup. A very nice supper dish can be made by taking a little cold veal and cold ham, cutting into small dice, with two hard-boiled eggs cut in slices, putting these in a dish, and pouring on them a little of the gravy to form a jelly. Warm in the oven in a shape, and turn out when cold.

SOUPS, ETC.

Soups are the substance of meat infused in water by boiling, and are of many different kinds, but may be divided into two classes—namely, *brown* and *white*. The basis of brown soups is always beef, while the basis of white soups is generally veal.

Liebig's Beef-tea or Brown Soup.—The following plan is that proposed by Baron Liebig for obtaining a soup which shall contain the whole, or nearly the whole, of the nutritious elements of the flesh employed: 'When one pound of lean beef, free of fat and separated from the bones, in the finely chopped state in which it is used for beef-sausages or mince-meat, is uniformly mixed with its own weight of cold water, slowly heated to boiling, and the liquid, after boiling briskly for a minute or two, is strained through a cloth or sieve from the coagulated albumen and the fibrin, now become hard and horny, we obtain an equal weight of the most aromatic soup, of such strength as can be obtained even by boiling for hours from a piece of flesh. When mixed with salt, and the other usual additions by which soup is usually seasoned, and tinged somewhat darker by means of roasted onions or burnt sugar, it forms the very best soup that can be prepared from one pound of flesh.'

Hare Soup.—Take a fresh hare, and, when skinned, wipe it well with a cloth. Cut it open, and take out the entrails, taking great care not to lose any of the blood. Then cut the body into separate pieces, and put them in a pot with two or three quarts of water, along with any blood that may have run out. Put into the pot also two or three pounds of beef, previously browned in a stew-pan, and cut into pieces, likewise a sliced carrot, turnip, and onion, two sticks of celery, a few sprigs of thyme, a few Jamaica peppercorns, a few cloves, and four table-spoonfuls of flour mixed with cold water. Keep stirring till it boil, and let it boil for an hour and a half. When this is done, take the best pieces of the hare, which are the back and upper joints of the hind-legs. Lay these aside. Let the soup boil for other two hours. Then take out the remainder of the meat, and cut it off the bones, and pound it in a mortar, or otherwise mash it well. Put the meat thus pounded back into the soup, and strain the whole through a hair-sieve. Put the soup so purified into the pot, along with the best pieces of the hare which were laid aside, also two table-spoonfuls of ketchup. Boil this for half an hour; then add pepper and salt, and serve with the pieces of hare in the tureen.

Mock-turtle Soup.—This is made with a calf's head. It is best to get the head ready scraped and cleaned from the butcher, but with the skin on. If it be got in an uncleaned state, wash it, and put it into a pot with cold water, and boil it for a short time till the hair is loosened. Then scrape off the hair, split the head, clean it thoroughly, and take out the brains. The head is now supposed to be clean, and ready for making the soup. Put it into a pot with considerably more water than will cover it. Skim it frequently as it warms, and let it boil gently for an hour. Take out the head, and when it has cooled, cut the meat off into handsome pieces of about an inch square. Scrape and cut the tongue in the same manner. Lay all these pieces aside. Then put into the water in which the head was boiled about three or four pounds of shin of beef and a knuckle of veal, with the bones broken. Add to this four or five onions, a carrot and turnip sliced, a small bunch of sweet herbs, and some black and Jamaica pepper, whole. Add also the brains, after you have boiled them separately in a cloth, and pounded them. With all these additions, let the soup boil slowly for four or five hours; after which, strain it, and when cool, take off the fat. Take a quarter of a pound of fresh butter, and melt it in a stew-pan; when melted, put in two handfuls of flour, and let it brown, stirring it all the time; add a little of the soup, a sprig or two of sweet basil, and a few heads of parsley. Boil this for a quarter of an hour; strain it through a sieve; then put this, the pieces of meat, and the soup, all together, and boil it for an hour. Add two table-spoonfuls of ketchup, the juice of a lemon, Cayenne pepper, and salt to taste. It is usual to put in at the same time four glasses of sherry wine. When dished in a tureen, put in two dozen of egg-balls.

Egg-balls for mock-turtle soup are made as follows: Boil four or five eggs till they are quite hard. Take out the yolks, and beat them in a mortar, with salt and Cayenne pepper. Make this into a paste with the white of one or two raw eggs. Roll the paste into balls the size of small marbles. Roll them in a little flour, and either fry them in butter or brown them before the fire, being careful to keep them whole and separate. They are now ready for being put into the soup.

Sheep's Haggis.—This Scotch dish is not composed in all cases of exactly the same materials. Some put minced tripe in it, others put no tripe. The following is the most common, and, we believe, the best manner of making it: Procure the large stomach-bag of a sheep, also one of the smaller bags called the king's hood, together with the pluck, which is the lights, the liver, and the heart. The bags must be well washed first in cold water, then plunged in boiling water, and scraped. Great care must be taken of the large bag; let it lie and soak in cold water, with a little salt, all night. Wash also the pluck. You will now boil the small bag along with the pluck; in boiling, leave the windpipe attached, and let the end of it hang over the edge of the pot, so that impurities may pass freely out. Boil for an hour and a half, and take the whole from the pot. When cold, cut away the windpipe, and any bits of skin or gristle that seem improper. Grate the quarter of the liver—not using the remainder for the haggis—and mince the heart, lights, and small bag very fine, along with half a pound of beef-suet. Mix all this mince with two small tea-cupfuls of oatmeal, previously dried before the fire, black and Jamaica pepper, and salt; also add half a pint of the liquor in which the pluck was boiled, or beef-gravy. Stir all together into a consistency. Then take the large bag, which has been thoroughly cleansed, and put the mince into it. Fill it only a little more than half full, in order to leave room for the meal and meat to expand. If crammed too full, it will burst in boiling. Sew up the bag with a needle and thread. The haggis is now complete. Put it into a pot with boiling water, and prick it occasionally with a large needle, as it swells, to allow the air to escape. If the bag appears thin,

tie a cloth outside the skin. There should be a plate placed beneath it, to prevent its sticking to the bottom of the pot. Boil it for three hours. It is served on a dish without garnish, and requires no gravy, as it is sufficiently rich in itself.

Lamb's Haggis.—This is a much more delicate dish, and less frequently made than a sheep's haggis. Procure the large bag, pluck, and fry of a lamb. The fry is composed of the small bowels, sweetbreads, and kernels. Prepare the bag, as in a sheep's haggis. Clean thoroughly the small bowels and other parts; parboil them, and chop them finely along with a quarter of a pound of suet. Mix with dried oatmeal, salt, and pepper, and sew the mixture in the bag. Boil it, and attend to it in the same manner as a sheep's haggis.

SAUCES AND FLAVOURS.

Sauces are liquid preparations, to be used in giving a flavour or relish to dishes, and are of various kinds. A number are formed of melted butter, with an infusion of some other ingredients; others are in the form of gravies drawn from fresh juicy meat; and a third kind are composed partly of water, and some preserves, condiments, or spices. There is little merit in making a good sauce when a person has good and proper materials to make it with. The chief merit consists in furnishing a fine flavour from inadequate materials; as, for instance, giving a rich flavour of meat to a mass of potatoes, or some other plain dish, when no meat has been employed. This can only be done by knowing the qualities of various vegetable products, and how these may be made to resemble the juices of animal food. The vegetable products of which by far the most can be made by a skilful cook are onions, mushrooms, and carrots. Onions and mushrooms alone furnish the most effectual substitutes for animal juices, and may be dressed so exquisitely as hardly to be distinguished from the gravy of beef.

Onion Flavour.—Onion flavour is made by stewing. Take several large onions, and remove the thin outer film from them. Put them in a sauce-pan with a little salt and flour, and a small piece of butter or dripping, to prevent their burning. Cover them quite close, and set by the fire to brown and stew gently. Two hours will dress them, and at the end of this time they will be quite soft, and, with the addition of a little water, they will yield a rich gravy. This may be used to fry potatoes with, or to flavour any other dish.

Mushroom-sauce.—Pick out the stems, and skin the mushrooms and the stems. Cut them in small pieces, and wash them. Then put them in a sauce-pan, with rather more water than will cover them. Let them stew gently for about half an hour, or till they are soft. They will now have yielded a fine rich sauce. Stir in a little flour and butter kneaded together, and season with pepper and salt. This preparation may be eaten with potatoes, the same as meat; it also forms an excellent sauce to many dishes.

Melted Butter.—This must be made of fresh butter. Cut down the butter into small pieces, and put them into a small sauce-pan with cold water, in the proportion of an ounce of butter to a table-spoonful of water. Throw in flour from a dredger with the one hand, while with the other you turn the sauce-pan rapidly round, so as to cause the flour to mix without lumping. A small quantity of flour is sufficient. You now for the first time take the sauce-pan to the fire, and continue turning or shaking it till the butter is thoroughly melted. When it boils, it is ready; it should then have the consistency of rich cream. If it should oil in making, it may be partially recovered by putting a little cold water into it, and pouring it several times into and out of a basin. This sauce is the foundation of a number of other sauces, various additions being made to it for the sake of variety.

Onion-sauce.—Skin the onions, and boil them in plenty of water. When soft, take them from the water, and chop them very fine. Melt butter as above, stir them in, and season with a little pepper and salt.

Egg-sauce.—Boil three or four eggs till they are quite hard. Peel and chop them, and then stir them into melted butter. Season with pepper and salt.

Caudle-sauce for Plum-pudding.—Melt butter, as above directed, and stir into it a glass of sherry, half a glass of brandy or rum, a little sugar, grated lemon-peel, and nutmeg. Do not let it boil after the spirits have been added.

Lobster and Crab Sauce.—Melt the butter, as above directed. Pick out the meat of a boiled lobster or crab; chop it down very fine, and put it amongst the butter. Season with Cayenne pepper and salt. If the lobster be procured raw, with berries or spawn on the outside, these should be taken off previous to boiling, and being mashed in a little cold water, may be added to the sauce after the lobster is put in. By boiling a little, the whole will become a bright red. This forms an improvement on common lobster-sauce.

Mint-sauce.—Take the leaves of fresh green mint. Wash them in boiling water, and after drying them, chop them very fine. Mix them with vinegar, and add a little sugar.

Beef-gravy.—A pound and a half of beef will make a pint of good gravy. Cut the beef in slices, or score it very deeply. Place it in a sauce-pan, with a bit of butter to prevent it from sticking, and a sliced onion. Brown the meat gently, being careful not to let it burn. Cover it closely, and let it stand beside the fire for about half an hour, to allow the gravy to run from the meat. Then put in about a pint of hot water, and let it boil slowly for an hour and a half, with some whole pepper. Some persons put in to boil along with it a piece of bread toasted hard and brown, which thickens the gravy a little, and adds to its richness. Season with salt, and strain it through a hair-sieve.

To make a Stuffing.—Roast veal, fowls, turkey, and some other things require a stuffing. These stuffings have been alluded to in various recipes in the preceding pages, and may here be expressly defined. Take a quarter of a pound of the crumbs of stale white bread, a quarter of a pound of chopped beef-suet or marrow, as much chopped parsley as will lie on a table-spoon, about half a spoonful of chopped sweet marjoram, and a little grated lemon-peel, pepper, and salt. Mix all these thoroughly together with one beat egg and a little sweet-milk. This forms a species of dough in sufficient quantity for a small turkey or large fowl.

Force-meat Balls.—These are balls formed of stuffing, used as a garnish for roast veal or veal cutlets. Make a stuffing like the above; but instead of being wet with one egg and milk, wet the mixture with two eggs. Roll the dough into small balls about the size of nutmegs. Roll them in flour, and fry them with a little lard, butter, or dripping. When required to be more savoury, the composition may be enriched with a little chopped ham, tongue, or sausage-meat.

Raspberry Vinegar.—Pour a bottle of vinegar on two quarts of raspberries—the wild are the best—and let them stand covered for two days. Put through a sieve, pressing the fruit very gently, add to each imperial pint of the liquor one pound of sugar, boil for seven minutes, take off the scum, and when cool, bottle for use.

Raspberry, Gooseberry, and other Jams.—Pick and clean the fruit well, and put on with an equal weight of good soft sugar and a very little water. Boil for twenty minutes, and pot when cool.

Pickles.

Red Cabbage.—Take off the outer leaves, and cut the cabbage into narrow straws. Sprinkle salt over them, and let them lie with a weight on them for two days. Wring the water out of them with a towel, put

then in a jar as much boiling vinegar, seasoned with black and Jamaica pepper, ginger, and a few cloves, as will cover them. Let them stand for twelve hours covered up in a cool oven. *Onions*.—Skin as many small onions as are wanted, throw them into salt and water as they are skinned, and scald them in this. Let them stand in the brine all night. Next day, drain, and pour on them boiling vinegar, which has been seasoned with ginger, white pepper, and mace. *Beet-root* must be boiled till soft—taking care not to break or cut off the fibres, as by doing so the colour would be spoiled—cut in slices, and the boiling vinegar with the spices poured over it. *Common Green Cabbage* should be parboiled, cut into small pieces, dried before the fire, and then have the boiling vinegar and spices poured over it. *Walnuts* make a very useful pickle, as the juice—called walnut ketchup—makes an excellent seasoning for hashes, stews, boiled mutton, &c. Gather the unripe walnuts, prick well with a bodkin, steep in strong brine for ten or twelve days, renewing it every three days. Rub them smooth, and pour boiling vinegar over them, seasoned with pepper, horse-radish, and mustard-seed. They require to be kept for a long time before they are soft and ready for use. The common vinegar sold by druggists, which is mostly diluted pyroligneous acid, answers very well for making pickles.

FISH.

Fish are dressed in a variety of ways, according to taste. They are boiled, broiled, baked, stewed, and fried; but the most common modes of preparation are boiling and frying—boiling when required to be done in a plain way, and frying when a high relish or flavour is to be given to them. In all modes of preparing fish, much care is required to prevent them from being broken or disfigured.

To fry Trouts or similar Fish.—Trouts of a moderate size are dressed whole, and frying is the best mode of preparation. Take the trouts and clean out and scale them. Dust them with flour or oatmeal, and put them in a frying-pan with hot dripping or lard. Turn them, so as to brown them on both sides. Lift them out and serve them on a dish; they will be improved by laying a napkin under them, to absorb the grease. In the country parts of Scotland, trouts are rubbed with oatmeal instead of flour, and some reckon that this improves the flavour.

To dress a Cod's Head and Shoulders.—Take a cod's head and shoulders in one piece, which clean, and let lie among salt all night. When you are going to dress it, skin it, and bind it with tape, to keep it firm. Put it in a fish-kettle, back upwards, with plenty of cold water, a handful of salt, and a little vinegar. Let it heat slowly, and boil for about half an hour. Then let it lie on the drainer across the top of the kettle, for the water to drip from it. After this, place it, back upwards, on the dish in which it is to be carried to table, cutting and drawing away the tapes very carefully. Brush it over with beat egg, strew crumbs of bread, pepper, and salt over it, and stick pieces of butter thickly over the top. Set it before a clear fire to brown. A rich oyster-sauce, made with beef-gravy instead of water, and highly seasoned with Cayenne pepper, salt, and ketchup, is poured in the dish around the fish.

To dress a Middle Cut of Cod.—Clean the piece of cod, and make a stuffing of bread-crumbs, parsley, and onions chopped small, pepper and salt, a bit of butter, moistened with egg. Put this stuffing into the open part of the fish, and fix it in with skewers. Then rub the fish over with beat egg, and strew crumbs of bread, pepper, and salt over it. Stick also some bits of butter on it. Set it in a bachelor's or Dutch oven before the fire to bake. Serve with melted butter or oyster-sauce.

To boil Haddocks, or a cut of Cod.—This is the simplest of all operations. Clean the fish well, and wash and boil with a little salt in the water, the first for twenty minutes or half an hour, the other for about three-quarters of an hour. Eat with oyster-sauce, or melted butter and ketchup.

To dress Haddocks.—This is a most delicious dish when well prepared. Take pretty large haddocks, which clean and wash well. They will be firmer and better if they lie for a night in salt. When to be dressed, wash them and dry them. Cut off the head, tail, and fins; then skin them, being careful not to tear the flesh. Cut the flesh neatly from the bone, and divide each side into two pieces. Dust them with flour, dip them into beat egg, and strew bread-crumbs over them. Fry them in a frying-pan, with a sufficiency of hot dripping or lard to cover them. Be careful that the dripping is not hot enough to scorch the fish. The way to ascertain the proper degree of heat of the fat, is to dip a thin slice of bread into it, and when it makes the bread of a light-brown tinge, put in the fish. If the fat be too hot, it will make the bread of a deep brown. Turn the pieces carefully, so as to brown both sides, and when done, lay them before the fire on a drainer for a few minutes. Serve in a dish, garnished with parsley. Sauce—oyster-sauce, or plain melted butter. The fat in which haddocks are fried will answer the same purpose again, if put through a hair-sieve, and poured in a jar, and kept in a cool place.

To fry Skate, Soles, Flounders, Whitings, and Eels, or any other White Fish.—Skate and soles are skinned and dressed in the same manner as haddocks, but soles are fried whole, not cut in pieces. Flounders are fried in the same manner, whole, but do not require to be skinned. Eels must be skinned and cut in pieces.

To bake Haddocks.—Take two or three haddocks, gut and clean them, and lay them all night among salt. When to be used, skin them, and cut off the heads, tails, and fins. Make a stuffing of bread-crumbs, chopped onions and parsley, and a little bit of butter. Sew this into the bellies of the fish. Rub them over with butter, strew bread-crumbs over them, and bake them in an oven or before the fire.

Fish and Sauce.—Take two or three haddocks, gut and clean them, and lay them all night among salt. When to be used, skin them, cut off the heads, tails, and fins. Boil these trimmings for three-quarters of an hour in a little water. Brown a little flour and butter in a stew-pan, and then strain the liquor, and put it to the butter; add sliced onion, chopped parsley, salt, a little Cayenne pepper, and a spoonful of ketchup. When all this has been boiled for a few minutes, cut the fish in pieces, and let it boil gently till dressed.

To scallop Oysters.—Scald the oysters in their own liquor. Pick them out of the liquor, and lay them in a dish, or scallop-shells, or tins, strewing crumbs of bread mixed with pepper and salt over each layer, and finishing with crumbs. Moisten the whole with a small quantity of the liquor in which the oysters were scalded, and stick pieces of butter thickly over the top. Place the dish before the fire to bake. From ten to twenty minutes will be required, according to the quantity.

PIES AND TARTS.

Pies are of two kinds—meat-pies and fruit-pies or tarts. Both are composed partly of paste, and therefore a knowledge of making pastry is indispensable to the economical housewife and cook. For this operation, the hands should be washed very clean, and care taken to have the board for working upon smooth, clean, and dry.

Under the head of 'Beef-steak Pie,' directions are given for making a light and very wholesome paste, which also answers quite well for tarts, but it can be made a little richer if wished. Dripping, lard, or butter can be used. The first two are cheaper than the butter, but perhaps the best compound is equal parts of lard and butter mixed.

On taking pies from the oven, and while quite hot, the crust may be glazed with white of egg and water

beat together, or sugar and water laid on with a brush; or a little pounded sugar can be sprinkled on tarts before serving. When not used hot, tarts are the better of being slightly heated before using on the subsequent days. Cream may be used with all the tarts.

Icing for Tarts.—After tarts are baked, they are sometimes iced on the top, to improve their appearance. The icing is done thus: Take the white of an egg, and beat it till it is a froth. Spread some of this with a brush or feather on the top or cover of the tart, and then dredge white-sifted sugar upon it. Return the tart to the oven for about ten minutes.

Rhubarb Tart.—Take as much rhubarb as wanted—Victoria is the best kind—skin and cut up into small pieces, fill the pie-dish, and add sugar, a very little water, and a little ground ginger and cinnamon. Put an old teacup in the middle of the pie-dish, as this prevents the juice boiling over. Cover and bake for about three-quarters of an hour.

Gooseberry Tart is made in the same way, the gooseberries being cleaned, and the heads and stems picked off. When the gooseberries are young, no spices are required. Rhubarb and gooseberries make an excellent mixture.

Apple Pie is made with the same seasonings, or with a little pounded cloves, or grated lemon-peel.

Raspberry, Blaeberry, Cranberry, and other Tarts are made in a similar way, but require no seasonings. All require to be picked and wiped, and to have sufficient sugar to sweeten them. The raspberries make an excellent mixture with rhubarb, and the blaeberries with rhubarb or raspberries. Red, black, and white currants, plums, &c., may all be used in the same way. The wild raspberries are the highest flavoured.

Stewed Rhubarb, Apples, Gooseberries, &c., are prepared in the same way as for tarts, and are stewed with sugar, a very little water, ground cinnamon and ginger, and are eaten coldish with cream.

Mince Pie.—Mince pie is a composition of meat, fruit, various spices and seasonings, and also spirits. The following is a properly proportioned mixture: Mince a pound of beef-suet, and a pound of roast-beef, or dressed fresh bullock's tongue; also a pound of apples pared and cored, minced separately from the suet and meat; a pound of currants washed and picked, a pound of stoned and chopped raisins, an ounce of ground cinnamon, half an ounce of ground ginger, an ounce of orange, and an ounce of lemon-peel, and a little salt; half a pound of raw sugar, one nutmeg grated, two glasses of brandy, and two of sherry. Mix all these ingredients together, and lay the bottom of your dish or small tin pans with paste; fill these with the mince, and then cover them with puff-paste. Put in the oven, and bake for half an hour. If the whole of the mixture be not used, what remains over will keep for a long time if placed in a close jar. Some persons do not put any meat in their mince pies.

Open Tarts.—These are tarts without covers, made in flat dishes. Cover the bottom of the dish with a paste, and cut a strip of it and lay round the edge of the dish. Fill in the centre with any jam or preserved fruit. Decorate the top of the jam with narrow bars of paste crossed all over, or stamped leaves. Bake for half an hour.

If there is any paste over, a very good plain tart may be made by spreading with fine treacle, dusting this with ground cinnamon, doubling up like a puff, and firing for a few minutes in the oven. Eat with cream or milk and raspberry vinegar.

PUDDINGS AND DUMPLINGS.

Care should be taken in making puddings to have the suet and the eggs which are put into them perfectly fresh. If there be any doubt of the freshness of the eggs, break each individually in a teacup, for one bad egg will spoil the whole. The cloths used for puddings should be of tolerably fine linen. Let them be carefully washed after using, and laid aside in a dry state, ready for the next occasion. Before putting the pudding into the cloth, dip the cloth in boiling water, and after the water has run from it, spread it over a basin, and dredge it with flour. Every pudding should be boiled in plenty of water, so as to allow it room to move freely; and it must be kept constantly boiling. It is a general saying among cooks, that a pudding *cannot be too well boiled;* and it is certain that there is much more danger of boiling it too short than too long a time. When you take the pudding from the pot, plunge it for a few seconds into a jar of cold water. This will chill the outside, and allow the cloth to be taken away without injuring the surface. The best way to dish a pudding is to place it with the cloth in a basin, then open the cloth, and lay the face of the dish upon the pudding; turn the whole upside down, lift off the basin, and remove the cloth.

Dumplings used formerly to be considered a very indigestible kind of food. By using the baking-powder, however, they can now be made light and wholesome. The paste, as formerly described at p. 757, is made by mixing a pound of flour with a heaped tea-spoonful of Borwick's Baking-powder, adding a quarter of a pound of lard or dripping, or half a pound of suet, making a paste of this with a small tea-cupful of water—hot, when suet is used—lining the dish with the paste, and enclosing with it the fruit, &c., and boiling in a cloth for two and a half to three hours. Rhubarb and gooseberries, blaeberries, or these mixed, and apples, prepared and sweetened as for tarts, and seasoned with nutmeg, answer very well. They are often eaten with a little nutmeg grated on them at table, and a bit of butter added; or they may be eaten with the addition of cream, or a sauce made of butter, a little water and milk, sugar, cinnamon, nutmeg, &c., to taste, and a glass of sherry wine, or half a glass of brandy or rum. No seasoning is needed when blaeberries are used, and cream is their best sauce.

The plain paste, made according to the directions at p. 757, with a quarter of a pound of suet to the pound of flour, can be formed into small dumplings, and boiled without any cloth for about an hour and a half. They are eaten with treacle and vinegar, or they are cut in slices, served round roast-beef, and eaten with it.

A *Roll-dumpling* is made with the same paste as above, rolling it out flat to about a quarter of an inch thick, spreading on it, but not quite to the edges, gooseberry or raspberry jam, marmalade, or other preserved fruit, rolling in a cloth, and tying tightly, boiling for an hour and a half, and serving with a sauce as above.

Yeast-dumplings are much used in some quarters where bread is made in the house, or where the dough can easily be got from the baker. Balls of dough, the size of the hand, are put in boiling water, and boiled for about twenty minutes. They should be eaten with butter and treacle, sugar and vinegar, or raspberry vinegar, the moment they are ready; and they are known to be ready when a fork stuck in them comes freely out.

Plain Rice-pudding.—Take a tea-cupful of rice, wash clean, put in a dish with three breakfast-cupfuls of milk, two tea-spoonfuls of sugar, a little salt, and a little ground cinnamon. Set in a very cool oven, or on the girdle, and let the whole simmer for three hours. Eat plain, or with raspberry jam and a little raspberry vinegar, or gooseberry jam, and cream or milk.

Semolina or Manna-croup Pudding.—Take half a pound of semolina, and put it in a pan with an imperial pint of milk, and the same of water, a bit of butter, a very little salt, and a table-spoonful of sugar. Keep stirring, and boil for ten minutes; season with five drops of essence of almond, and twenty drops essence of lemon. Serve in a dish with bits of jam round it, or in a shape, and eat warm or cold, as above, with jam, cream, &c.

Rice-shape.—Take a pound of whole rice, wash well, and put in a pan with a quart of milk, the same of water, a bit of butter, a little salt, and six or eight pieces of lump-sugar; and simmer very slowly with closed cover, without touching, for three hours. Flavour as above, when ready, with essences of almonds and lemon; press into a shape, and eat cold with jam, as above, and cream.

A plainer mode of eating rice is to prepare it as directed for a curry, p. 758, and eating with jam and cream, as above.

Plum-pudding.—A plum-pudding may be made either rich or plain, according to the quantity of fruit and spices put into it. The following is the direction for making what would be considered in England a *good Christmas-pudding:* Take a pound of good raisins, and stone them; a pound of currants, which wash, pick, and dry; a pound of rich beef-suet minced, and a pound of stale bread-crumbs, and half a pound of flour. Mix the bread, flour, and suet in a pan. Beat six eggs in a basin, and add to them about half a pint of sweet-milk. Pour this egg and milk into the pan with the suet and flour, and beat it well with a flat wooden spoon for some time. Then stir in the currants and rasins, mixing well as you proceed; mix in also a quarter of a pound of candied orange and lemon peel, cut in thin small pieces, an ounce of powdered cinnamon, half an ounce of powdered ginger, a nutmeg grated, and a little salt. Next add a glass of rum or brandy. The pudding is now made, and ready to be either baked or boiled, according to taste. If to be baked, butter your tin or basin, and put the pudding into it, and bake in an oven for an hour and a half, or nearly two hours. If to be boiled, pour it into a cloth; tie the cloth, allowing a little room to swell, if made of bread, and boil for six hours. Serve with caudle-sauce.

Carrot-pudding.—Take half a pound of suet, the same of flour, some bread-crumbs, currants, stoned raisins, ground ginger, and cinnamon, grated nutmeg, sugar, a very little salt, and one large carrot grated. Mix in a basin, moisten with a little milk, boil as above for four hours, and eat with the same sauce.

Currant-pudding.—An excellent family pudding may be made of the following ingredients: A pound of minced suet, a pound of bread-crumbs or flour, three-quarters of a pound of currants, washed and picked, a little powdered cinnamon and grated nutmeg, and a very little salt. Beat two eggs, and add as much milk to them as will wet the whole. Mix all together, tie in a cloth, as previously directed, and boil for three hours. Serve with caudle or any simple sweet sauce.

Bread-pudding.—Boil as much milk as will be sufficient for the pudding you want. When it begins to boil or rise in the pan, pour it upon crumbled-down stale bread in a basin. The quantity of bread should be as much as will thicken the milk to a stiff consistency. Cover it up for ten or fifteen minutes, to allow the bread to swell. Then beat or mash it up to make a fine pulp, stirring in a small piece of butter. Beat three or four eggs, a tea-spoonful of ground cinnamon, a little grated lemon-peel, and sugar according to taste. Stir this among the pudding. A little brandy or rum may be added; also a few currants, if required. The pudding may be either boiled or baked. If to be boiled, put it in a well-buttered pudding-shape or basin, with a buttered paper over it, and also a cloth over all: boil for an hour. If to be baked, put it into a buttered baking-dish, and bake in an oven for half an hour.

Rice-pudding.—Take a pretty large cupful of rice, pick it, and wash it well in cold water. Boil it in water for about five minutes. Drain the water off, and put it on again with as much milk as you require. Let it boil till the rice is quite soft, stirring it frequently, to prevent it from burning. When done, put it into a basin, and stir in a piece of butter, or some suet minced very fine. When cold, add to it four eggs, beaten, with a little ground cinnamon, grated nutmeg and lemon, and sweeten with sugar. All is to be mixed well together. It may be either boiled or baked, as directed for bread-pudding. The above composition may be enriched by using more eggs and less rice, also by adding currants, spirits, and candied orange-peel.

Custard-pudding.—Take four eggs, and beat them well with two table-spoonfuls of flour and a little cold milk. Season this with sugar, ground cinnamon, grated lemon-peel, and pour on a pint of boiling milk, stirring all the time. It may be either baked or boiled. By using more eggs, the flour may be omitted.

Bread-and-butter Pudding.—Cut several slices of bread rather thin; butter them on one side; put a layer of them in a pudding-pan or dish, and a layer of currants above; then another layer of bread; and so on till the dish is full. Beat four eggs, with a little ground cinnamon and nutmeg, also some sugar. Add milk to this, till there is sufficient to fill up the dish. Then pour it over the bread, and allow it to stand for a time to soak. It will now be ready for either baking or boiling, as directed for bread-puddings.

Tapioca-pudding—Sago-pudding.—Take a quart of milk, and put in it six table-spoonfuls of tapioca. Place it on the fire till it boil; then sweeten to taste, and let it simmer for a quarter of an hour. Stir it frequently, and be careful that it does not burn. Then pour it into a basin, and stir into it a little fresh butter and three eggs well beaten; you may now pour it into a buttered pudding-dish, and bake for about an hour; or, after adding another egg, boil it in a basin or mould for an hour and a half. Sago-pudding may be made in the same manner.

Batter or Yorkshire Pudding.—Take a quart of sweet-milk, and mix in it a large cupful of flour, making the mixture very smooth. Beat four eggs, and strain them into the batter. Add a little salt, and mix all well together. Butter your dish or tin, and pour the batter into it. Place the dish either before the fire under roasting meat, or under meat sent to the oven. The pudding, when done, easily shakes out of the dish into another dish to be carried to table. It should have a nicely browned appearance. When dressed before the fire, either turn the pudding, or place the dish a short time on the fire to brown the under side. It is eaten before or with the meat.

Pease-pudding.—Pick a quart of split pease—that is, remove all impurities, or discoloured pease, or shells. Tie them loosely in a cloth, leaving plenty of room for the pease to swell. Boil till they are soft, which may be in from two to three hours. Take the pudding from the water, and put it into a basin. Open the cloth, and bruise or mash the pease well. Mix in a piece of butter, with pepper and salt. Then tie it up tightly, and put it into the pot again, and boil for about half an hour. When ready, turn it out of the cloth into a vegetable dish. If properly managed, it will turn out whole.

Pancakes.—Take three eggs, beat up with a little pounded loaf-sugar, add a small table-spoonful of flour for each egg, and rub till smooth. Put in as much milk as will make the whole of the consistency of cream, three drops of essence of almonds, two of cinnamon, and eight of lemon. Put a bit of butter or dripping in the frying-pan; make hot, and pour in half a tea-cupful of the batter, so that it cover very thinly the bottom of the pan; and brown lightly. Slip a knife under the edge all round, and roll up, fold into three, and lay on the dish. Sprinkle a little pounded loaf-sugar, and eat very hot with raspberry vinegar. When put out in this way very thin, it is unnecessary to turn them.

German Pancakes.—Take a slice or two of a stale pan-loaf, cut half an inch thick; take off the crust, and cut into bits about two inches square; soak in milk for three minutes; have ready two eggs; beat up with a little ground cinnamon, nutmeg, and sugar; dip the bread in the beat egg, and fry on both sides till of a light-brown. Eat with raspberry vinegar.

MEDICINE–SURGERY.

ERROR in diet, drink, dress—in fine, the erroneous treatment of ourselves as organised beings—is sure, sooner or later, to be productive of bodily ailment. Even were we faultlessly nurtured as to food and clothing, and were we born with perfectly sound constitutions, still we are liable to injury from numerous external causes; such as weather, climate, accidents, &c.; hence the necessity either for remedial agents, in the shape of *medicines*, strictly so called; or for aid, in the form of *surgical* operations. A man, for instance, may be afflicted with some internal or external malady, and he has recourse to a medicament or healing substance, with the hope that it will remove his affliction, and restore him to health. Again, he may have received such bodily injury, or his malady may have assumed such a form, that an internal medicine would be unavailing, and he submits to the instrumental operations of the surgeon. Thus, it is customary to distinguish between the surgeon, physician, and the apothecary or chemist, whose business it is to prepare or compound drugs; and such distinctions are not without their advantages.

In the following pages, therefore, while separating Medicine from Surgery, we follow no technical distinction further than seems likely to facilitate the ordinary reader's comprehension of an art as necessary to his wellbeing as those which relate to his food and clothing. Our utmost aim is to convey to the class whom we more especially address a general notion of the science; those who seek for more will find themselves disappointed. To adopt the language of a recent medical writer: 'No one who reads herein is to expect that he is to find a whole body of surgery, or that he will be fitted thereby to set up for an amateur surgeon, capable of practising upon himself or his neighbours, for a vast deal must be passed by. Not that there are any "secrets of the prison-house" to be kept; but everything cannot be told, usefully at least, to general readers, for this simple reason—that were it set forth, they could not rightly comprehend it. Still, there is much to be mentioned which may be of good service on emergency, without interfering with the doctor.'

MEDICINE.

All those drugs which in some form or other are applied to the alleviation or cure of bodily ailments, are known by the name of medicines; and they consist for the greater part of substances prepared from vegetables and minerals, a few only being of animal origin. As to the history of the earliest employment of medicinal agents, no tribe is so rude as not to have discovered the remedial virtues of certain plants. Chance would probably determine, in the lapse of time, the uses of many. Indeed, at no very distant period, one of our most valuable medicines was discovered by mere accident. A quantity of Peruvian bark had been thrown as useless into a small well, out of which some soldiers afflicted with the ague had the good fortune to drink. To their own surprise, as well as that of others, they became rapidly well, and the cure, happily, was attributed to the right cause. In the same manner, a knowledge of many important medicinal articles has been attained, and occasionally some bold inquirer has arrived at the same end by actual experiment. As among the African and North American tribes of the present day, however, a great portion of the medical art of our forefathers lay in working on the fears and imaginations of the patients by means of pretended charms and incantations. The effects of mesmerism, and of homœopathic globules, in the treatment of disease, as well as of many other forms of quackery, are explicable through their influence upon the imagination—the faith or the fears of the sufferers.

The medicinal preparations of the ancients were taken almost entirely from the vegetable kingdom, though the Arabian school of medicine, which arrived at great eminence while the Saracens were masters of Spain, was well acquainted with several metallic remedies. The researches, however, of the chemists, or rather alchemists, of the dark ages, first brought fully to light the great value of the metals in the hands of the physician, and this credit these ingenious individuals are at least entitled to, though we may smile at their absurd attempts to transmute baser minerals to gold, or to find out the elixir of life. They made thus a most important addition to the number of medicines, and effected a change in the healing art which is felt to the present time. The liability of herbs to spoil by keeping, whether in the state of roots, leaves, or seeds, gave a great superiority to the mineral preparations, which retain their powers for a long period. At the time when they were first introduced, the sensation excited was so great, that the numerous believers in their virtues were called, in contradistinction to the admirers of vegetables, the chemical school. The discovery of the circulation of the blood founded a new set of philosophers, who maintained that the body was entirely framed upon, and regulated by, mathematical laws. Though this doctrine was supported by some eminent men, and for a short time superseded the chemical theory, yet its total failure to account, upon mechanical principles, for all or for any of the vital actions, soon caused it to fall into disrepute.

It is scarcely necessary to mention any other changes in the progress of the science of medicine, and indeed those taken notice of are of consequence only from their effects on the nature of the remedies for disease. During the eighteenth century, anatomy was prosecuted with deep attention, the nature of medicinal preparations closely investigated, and their number increased; the result of which was, the reduction of the practice of physic to principles more agreeable to reason and to truth. Men, too, partaking of the wide spread of knowledge during the period mentioned, began to object to nostrums when labouring under illness, and became reluctant to swallow a dose without being informed of the nature of the action, and the effects expected. Hence medicines, instead of being applied indiscriminately to every species of disease, were arranged into some sort of order, and classified according to their known or supposed operation. This is the most simple method of viewing the range of medicinal substances, and it is the one we shall adopt in the present instance—though the small space at our disposal, as well as the scope of the present observations, prevents more than an enumeration of the most common medicines.

MODES OF ACTION OF MEDICINES.

Some substances employed in the cure of disease act *mechanically*, and others *chemically*, on the system; but by far the greater proportion of them act *vitally*.

A medicine is said to act *mechanically* when its effect on the body is the same as that which it exerts over inanimate matter. Demulcents, for instance, or remedies taken to remove the acrid effects of some other substance, operate simply by coating the stomach with a gummy fluid, an action which is entirely mechanical. The *chemical* operation of medicines may be thus explained: When an acid and an alkali are mixed in a glass of water, they unite together, and form a third substance, a salt, having new properties altogether. The same chemical process takes place when sourness, or an acid, is neutralised in the stomach by soda, or any alkali. The *vital* action of medicines differs totally from the two former. In this case, the substances are absorbed into the blood, and are conveyed by the vessels of the heart to the quarter whither their nature determines them, and in which their special action is manifested. Diuretics, or medicines which stimulate the urinary organs, may form an example of vital action. From the stomach, the diuretic is absorbed into the blood-vessels, and carried to the kidneys, stimulating them to the secretion of urine, though by what process this fluid is there separated from the rest of the blood, we know not. Under these three divisions, then, *mechanical*, *chemical*, and *vital* agents, all the articles used in medical practice—technically, *materia medica*—are comprehended.

Although scientific medicine does not stoop to cheat the imagination of the patient, it does not ignore the beneficial assistance that may be afforded in the treatment of disease by the mental affections, and through the external senses. Thus, in nervous disorders, it recognises and avails itself of the soothing influences of quietness and of melodious or monotonous sounds. In fainting, hysterical attacks, &c., it operates upon the senses, stimulating the olfactory organ with ammonia, vinegar, &c.

Nervous and mental maladies are often observed to be influenced by various degrees of light or darkness, by change of scene, and by the degree in which hope or confidence in the measures adopted can be realised.

Alphabetical Classification of Medicines according to their Effects.

Antacids, as the name imports, are those medicines which correct acidity of the stomach and digestive organs. The stomach of many individuals is liable to a continued conversion of their food, particularly vegetable food, into a species of acid, which produces the annoying feeling called heartburn. This acid may be neutralised by any of the alkalies, and the process of relief is as purely chemical as if it were performed in a glass of water for experiment. The three alkalies, potass, soda, and ammonia, the alkaline earth magnesia, and carbonate of lime (chalk), are the most useful medicines of this description. The relief obtained from them is, as might be expected, merely temporary, since they do not prevent the generation of the acid anew. Antacids should in general be prescribed along with vegetable tonics, and in no case ought their administration to be long persisted in without occasional interruptions, as they cause thinness of the blood if used too long. It is further necessary to observe in what condition, and in what region, the acidity more particularly manifests itself, as all antacids have not precisely the same properties and modes of action. Thus, the best corrective for gaseous acidity in the stomach is found to be ammonia and its carbonate, and magnesia; and where acid exists in the urinary organs, potass and soda are preferable. Calcined magnesia is one of the simplest and best known of the antacids. It is employed in indigestion, attended with acidity of the stomach and constipation; in which cases it is generally preferred to the other alkalies, as being less irritant, and as the combinations which it forms with the free acids of the stomach are gently laxative. It is also administered with much advantage in the acidity attendant on infantile diseases.

Anthelmintics, also known as *Vermifuges*, are those drugs possessing the property of destroying worms, or expelling them from the intestinal canal. Other medicines, as the more active purgatives, may also effect this purpose. Among the more common vermifuges may be mentioned powder of tin, oil of turpentine, pomegranate bark, powdered fern-root, Corsican moss, and worm-seed. 'As the action of these remedies is merely temporary,' says Dr Neligan, 'it will be requisite, as soon as the worms are expelled, to employ means calculated to restore the digestive organs to a healthy state, and to correct that peculiar character of them which promotes the generation of intestinal worms. The means best calculated for this purpose are: Keeping the surface of the body warm by proper clothing; a light but nutritious diet, with a moderate use of common salt; and at the same time the administration of bitter tonics, with gentle aperients.'

Antispasmodics are used to remove spasms or convulsive contractions of the muscular fibre in the body, and are very similar in their action to the class Narcotics. Opium, ether, camphor, ammonia, chloric ether, valerian, galbanum, and asafœtida, with most of the narcotics (which see), are the antispasmodics generally in use.

Aperients or *Cathartics* is the general term for those numerous medicines which quicken or increase the action of the bowels. As they differ considerably in their effects, they are usually spoken of as *laxatives* or *aperients*—that is, gentle evacuents; *purgatives* when more powerful; and *drastics* when they are particularly powerful and energetic. Whatever be their energy, they may be arranged under three heads: 1. Those of an oily or saccharine nature; 2. Those which are derived from vegetables, such as resins and extracts; 3. And those formed by a combination of acids with earths, alkalies, and metals, termed neutral and metallic salts. The operation of all these three is of the character of an irritation upon the mucous or inner membrane of the bowels, though in their effects they differ considerably from each other. The first mentioned seem simply to discharge the contents of the bowels; the second appear to increase the quantity of matter evacuated, by stimulating the mucous membrane, and increasing the natural flow of mucus; while the third class produce evacuations of a watery consistence.

The principal purgatives of the *first* kind are, castor-oil, manna, tamarinds, and so forth. Castor-oil is one of the most useful and safe medicines of the purgative class. The others mentioned are exceedingly mild in their operation, and are generally employed merely to palliate or disguise the bad flavour of some stronger drug.

The *second* kind of purgatives includes aloes, scammony, jalap, colocynth, senna, and rhubarb. The general character of all these has been given above, though the rhubarb possesses one remarkable distinction from the others. It is supposed to act on the muscular membrane of the bowels, producing a natural discharge simply, and afterwards acting as a tonic.

The principal neutral and metallic salts, which form the *third* order of purgatives, are sulphate of soda, Epsom salts (sulphate of magnesia), cream of tartar (supertartrate of potash), phosphate of soda, and calomel (submuriate of mercury). The latter is the most universal in its application of all medicinal preparations. But in proportion to its usefulness, so is its danger when misapplied. The dose should be small, and combined with rhubarb, jalap, or scammony, as it has been found occasionally, when taken alone, even in a single dose, that salivation was produced. The frequent use of calomel as a common purgative is to be strictly guarded against—for it must be borne in mind that calomel is one of the most potent of drugs, either for good or for evil—and the less frequently it is taken

the better. With respect to the others, little can be added to the general description already given; it may be mentioned, however, that the pleasantest, though not the cheapest of all medicines, is the phosphate of soda, or *tasteless salts*.

As cathartics of some kind or other are very largely —perhaps too largely—used in this country, where there are so many sedentary and indoor employments, it may be well to transcribe a few remarks from one of the fathers of modern medicine on the subject: 'The operation of cathartics,' says Gregory, 'is dangerous to the weak, the irritable, the slender. It is also to be attempted with great caution, even by the gentlest medicines, in inflammation of the stomach and intestines, or when these are in a delicate state, as in dysentery or protracted diarrhœa. Too frequent repetition of purging, though at first necessary, does great injury, both to the whole system, which it weakens exceedingly, and especially to the intestines themselves, which it sometimes renders preternaturally feeble, tender, and irritable, but more frequently torpid and slow; whence proceeds constipation, and a necessity of having habitual recourse to cathartics. It also renders the blood thin and pale, in the same manner as too frequent blood-letting. . . . . But where necessary, due allowance should be made for the patient's idiosyncrasy, not only in regard to the nature of the medicine, but also to its quantity, mixture, preparation, and time of taking it. During the operation of cathartics, patients are very easily injured by cold, possibly not more by reason of the body being then weakened, than on account of the current of fluids being drawn off more than usual from the external parts: it is therefore proper at such a time to guard carefully against exposure.'

Astringents, as commonly defined, are substances which produce contraction and condensation when they come in contact with living matter; their mode of action, however, is rather obscure. Their power appears to depend in a great measure on the presence of the principle called tannin, and they produce their effect by bringing into closer contact the particles of the body to which they are applied, without in other respects affecting its mechanical structure. They are believed to be often of service in restoring tone to the stomach, and it is evident that their astringency will be of great advantage when any laxity of the surface of that organ exists; hence in many instances the most powerful tonics will be obtained from the class astringents. All the vegetable astringents contain tannin; and those most generally employed are preparations from gall-nuts, catechu, kino, oak-bark, logwood, and creosote. A number of the acids, and some of the salts, those particularly in which the acid preponderates over its base, as in alum, which is a compound of vitriol and the earth alumina, possess astringent properties, although they contain no tannin. Some of the metallic salts, as superacetate of lead (sugar of lead), and sulphate of zinc (white vitriol), are ranked in this class. Cold is also a direct astringent, and is often employed in this character with great advantage in checking bleedings. 'All the astringent medicines taken from the vegetable kingdom,' says Gregory, 'are so mild and safe, that they may be taken inwardly, and the use of them long continued without difficulty or danger, in larger or smaller doses, according to the strength of each; but those from the mineral kingdom cannot always be so employed; indeed, they are fitted more for external than for internal application.'

Carminatives are those medicines which produce the discharge of flatulence from the alimentary canal. This malady is more annoying than dangerous, though it rises occasionally to a most painful height. The warm essential oils, such as caraway, anise, or peppermint, and some aromatic stimulants, as cinnamon and ginger, are the carminatives in greatest repute.

Caustics are a class of substances employed to create artificial sores or ulcers, often employed for the purpose of relieving some deep-seated malady. The operation of caustics is considered chemical, being the result of some attraction between the animal body and the substance employed. The same action takes place on the application of caustics to a portion of the dead subject. Where suppuration is going on in any internal part, they are exceedingly useful in creating a drain on the surface of the body. The principal caustics employed in medicine are potass, blue vitriol, nitrate of silver, arsenic, and some preparations of mercury. The nitrate of silver, or lunar caustic, is the substance in most common use, chiefly on account of its great manageableness, in consequence of its solid form, its property of not deliquescing, and its mild but effectual action—the pain produced by it being but of short duration. There is also a milder action of substances that are usually denominated caustics. Thus, nitrate of silver (lunar caustic), when dissolved in water, exerts very beneficial astringent or sedative action upon the skin and mucous membrane, according to the strength of the solution. From two to five grains, dissolved in one ounce of water, forms a most valuable lotion in most common kinds of inflammation of the eye. A stronger solution, from half a drachm to a drachm in the ounce of water, may be very successfully painted on the inside of the throat, in inflammations of that part. Nitrate of silver, sulphate of copper (bluestone), concentrated acetic acid, and nitric acid, are employed as caustics for the destruction of warts; and only require care that they do not spread to adjacent parts.

Counter-irritants—known also as vesicants and rubefacients—are substances which produce redness, vesication, or inflammation, when applied to the skin. The extremities of the vessels which convey the blood from the heart over the body, are supposed, when they terminate on the skin, to divide into minute tubes, one kind of which carries the red globules, and another the colourless serum of the blood. When strong stimulants, such as mustard or Spanish flies, are applied to the skin, they are supposed to excite these minute vessels so powerfully, that those which contain serum become filled with red globules; hence the term *rubefacients*. This can only be produced during an extraordinary flow of blood to the part, and is the cause of the redness consequent on the application of mustard cataplasms or blisters. A blister is simply a rubefacient allowed to remain on the skin until the deeper layer of it becomes affected, and pus or serum exudes. Like caustics, blisters are exceedingly useful in substituting a superficial inflammatory action for one existing in some deeper and more dangerous seat, and they are hence called *counter-irritants*. The principal substances employed in exciting cutaneous inflammation are Spanish flies, mustard, tartarised antimony, ammonia, turpentine, and a few other drugs of a stimulant nature. The Spanish flies are almost exclusively used in blistering; and mustard, as a rubefacient, is held in a similar degree of estimation.

Demulcents—known also as *emollients*, *diluents*—are a class of medicinal agents the operation of which seems entirely mechanical. A poultice is applied externally to soften an inflamed or irritated part, and with exactly the same views are demulcents or diluents used to soothe any irritation of the alimentary canal. Solutions of gum, and sirups, with barley-water, rice-water, and other farinaceous drinks, are employed for this purpose. Iceland moss (*Lichen Islandicus*), liquorice-root, almonds, figs, sugar, marsh-mallow, linseed, and others, are included in the class of demulcents.

Emollients are generally ranked under two great classes—the oleaginous and mucilaginous. Whether taken internally, or applied externally as Fomentations (which see), their action is simple and easy to be understood: the solid parts are rendered elastic or resisting, but more flexible; and of consequence some parts, which

previously hardly admitted of motion, are afterwards moved with much greater ease. 'Of all medicaments of this kind, by far the most powerful and certain is pure water, especially when warmed; for the innumerable decoctions, fomentations, and infusions which are so frequently prescribed, and so much celebrated for their emollient qualities, are generally nothing else, and have no other virtue than pure warm water.' Oily and mucilaginous emollients have one advantage over pure water, that they are not so soon dissipated by evaporation.

Fomentations are warm fluids, applied for the purpose of encouraging perspiration on the skin, and thereby to diminish inflammation, and to render the skin yielding, so that the swelling which accompanies inflammation may be less painful, by the greater readiness with which the skin yields than when it is harsh and dry. The usual practice, therefore, of rubbing, dabbing, or pressing, is improper. The patient must be as well defended as possible from exposure to wet, by having something placed under him; and then a piece of thick flannel, or blanket, after being saturated in the warm fomentation, is to be instantly wrung, and laid liberally on the part of the body affected, and covered with oiled silk or a jack-towel, to keep in the warmth. This process is to be repeated every ten minutes or so, for hours if necessary. The foot or hand may be fomented by mere immersion, the heat of the fluid to be kept up by the addition, from time to time, of more which is hot. Warm water, as already stated, makes of course the readiest fomentation, and is generally the best.

Diaphoretics are those remedies which promote the insensible perspiration; *Sudorifics*, such as produce profuse perspiration or sweating. These two classes of remedies are very closely connected, and scarcely, if at all, admit of being distinguished; the effects differing rather in degree than in kind. With regard to their action, it seems to be sympathetic rather than direct: nausea and vomiting produce profuse sweating; sudden fears, and other mental emotions, do the same thing; and all the diluents, stimulants, sedatives, and emollients act less or more in this way. Among the simplest diaphoretics may be ranked whey, gruel, barley-water, and other warm drinks and infusions. 'Among the most excellent and salutary diaphoretic remedies,' says Dr Gregory, 'is deservedly reckoned proper bodily exercise; for when moderate, it accelerates the circulation, and eminently promotes perspiration: when more violent, it generally induces a profuse sweat, even in those persons who can scarcely be compelled to sweat by the medicines commonly used. Among the most active *sudorifics* may be enumerated warm drinks; the warm bath; the preparations of antimony, including James's powder; Dover's powder (compound ipecacuan powder); the preparations of ammonia; and all medicines generally which nauseate the stomach. Probably, of all these, Dover's powder is the best. Sudorifics, in almost all cases, when early used, prevent the effects of colds, which, when neglected, prove so often fatal in their consequences. During the administration of sudorifics, it is essential that the surface of the body should be kept warm; and for this purpose, a bad conductor of heat, such as flannel, should be employed. Care also must be taken to avoid the application of cold, either by exposing the surface of the body to cold air, or by the use of cold drinks while the perspiration continues, or for some time after it has ceased; lastly, when it is wished to check the perspiration, this must be done gradually, by drying the surface of the body with dry warm towels, by diminishing the covering, and by cautiously exposing the hands and arms to the air.

Diuretics are those medicines which operate in promoting the flow of urine, by stimulating the action of the kidneys, the organs which secrete it. This class is very numerous, though the manner of their operation, like that of all the other vital agents, is not thoroughly understood. 'In whatever manner the action of diuretics is produced, the general effect is to diminish the watery part of the blood, and by this means promote the absorption of fluid effused into any of the cavities or into the cellular membrane. Hence dropsy is the disease in which they are principally employed; and when the discharge of urine can be excited by their administration, the effused fluid is in general removed more speedily from the system, and with less injury to the patient, than by any other method.' The diuretics chiefly employed in practice are squills, foxglove, juniper-berries, potash, cream of tartar, acetate of ammonia, nitric ether, and Spanish flies. All these act powerfully on the urinary organs—those in highest repute being squills, foxglove, juniper, and cream of tartar. The first and the last of these are the most efficient, being more certain in their effects than the others. (Foxglove and Spanish flies, being powerful poisons, should not be used by other than professional direction.) The action of diuretics is much affected by the state of the skin; hence the common rule, during their exhibition, to keep the surface of the body cool, and to promote the operation of the dose by the use of simple diluent drinks. Further, from the nature of the above-enumerated substances, it is sufficiently clear that some of them are decidedly heating, others refrigerant; some considerably increase the acrimony of the urine, others diminish and blunt it: so that it is quite evident that all of them cannot be equally adapted to every disease.

Emetics are substances administered for the purpose of producing vomiting. It may be supposed, from their being received into the stomach, and acting directly and speedily upon it, that there is no absorption into the blood necessary. Tobacco, for instance, taken into the stomach, excites vomiting; but it is from its reception into the circulation; because, if the tobacco be laid on the arm, the same effect will be produced. Some emetics, indeed, appear to act principally on the muscular covering of the stomach, exciting it to contraction, and thereby causing the expulsion of the contents. Most of them, however, simply produce nausea, which causes the inversion of the receptacle of the food. The most active emetics employed in medicine are tartar-emetic, ipecacuan root, chamomile flowers, mustard, and sulphate of zinc. The first two of these are most commonly used; the second of the two being the gentlest, and perhaps on that account the safest, in ordinary cases. 'Emetics should be employed with great caution where there are symptoms of determination of blood to the cerebral organs, in consequence of the obstruction of the circulation which is occasioned during the act of vomiting; for the same reason also they ought not to be administered in diseases of the large arteries, as in aneurism. From the violent action of the abdominal muscles which is caused, the act of vomiting is attended with great risk in the advanced stages of pregnancy, in hernia, and the like.' Frequent vomiting is very injurious to the body, as it weakens the stomach, of course spoils the digestion, and thus in some measure becomes necessary. The operation is more easy with a full than with an empty stomach; hence the advantage of drinking pretty copiously during the exhibition of emetics. It is often of advantage, especially in very infirm patients, or those who have been much agitated, to give an anodyne after vomiting, to compose such agitation, procure sleep, and recruit the health.

Expectorants, or *Pectorals*, as they are sometimes termed, are substances used to promote the expulsion from the lungs of those fluids which are secreted during colds, and lodge there, causing difficult breathing, and sometimes ending in injury of their structure. Thus those remedies which promote expectoration are of great consequence to health, though often neglected. The principal medicines of this class are antimony, squills,

ipecacuan, balsam of Tolu, and gum ammoniac. Sirup of squills is the preparation in greatest use, forming one of the best expectorants we possess for the pulmonary affections of children, in doses of from ten to thirty minims. To these may be added all emetic substances which, by their mechanical action, dislodge accumulated secretions from the respiratory organs, and thus frequently become valuable agents in the treatment of diseases requiring the application of expectoral drugs. To these may be added all Diaphoretics, the inhalation of steam of warm water, which acts as an emollient, and riding on horseback, which has been much recommended.

Febrifuges are medicines employed to remove fever. They necessarily will vary nearly as much as the characters or types of fevers vary. Thus, simple fever is removed by aperients and salines, or diaphoretics—for example, a few doses of James's powder, or Dover's powder. Fevers, however, of a lower character, such as the typhoid or nervous fever, more frequently require the administration of stimulants. Again, fevers of the intermittent or periodical type, such as ague, are cured by quinine. The word febrifuge, therefore, is obviously one of very wide application.

Narcotics—known also as *Anodynes*, *Soporifics*, and *Hypnotics*—are those substances which tend to remove irritation or pain, inducing in general a state of repose. Before this quieting effect is produced, however, there is a primary excitement of short duration, which is well exemplified in the case of opium. *Sedatives*, viewed as a separate class, are believed to allay pain and promote sleep, without possessing any stimulating qualities. Unless where excessive pain is present, narcotics may be regarded as a class of medicines *only to be used with great caution, and never free from danger.* Opium and its preparations, lettuce extract, henbane, foxglove, Indian hemp, hemlock, belladona, and tobacco, are some of the strongest narcotics. It is difficult to say which of these is the safest: 'idiosyncrasy,' says Dr Neligan, 'has a remarkable influence on the effects of narcotics: we meet with some individuals almost insensible to their action; while in others, small doses produce a dangerous stupifying effect, or in some instances give rise to a degree of excitement amounting to furious delirium. But habit influences the action of narcotics on the system more than any other circumstance—their power being diminished in an extraordinary degree by repetition. Where, therefore, their continued administration is required, it will be necessary gradually to augment the dose, in order to produce their usual effects. The influence of age on their action must be also borne in mind in their administration, *the young being much more susceptible to their influence than individuals of maturer age.*' It is, indeed, scarcely ever safe to administer opiates to infants. *Sedatives* are those substances which directly or primarily depress the vital powers without inducing any previous excitement. From their effects, which are directly contrary to those of stimulants, they are sometimes termed *Contra-stimulants;* occasionally, *Calmatives.* With regard to the distinction which is made between them and narcotics, Dr Neligan remarks: 'Were we merely to theorise on their mode of action, it would be perhaps difficult to draw an exact line of distinction, but when we come to consider the remedial powers of the medicines classed under each head, it will, I think, be at once evident how *practically* essential it is that we should recognise this as an especial class of remedial agents.' Among sedatives are to be found the most potent poisons. The diseases in which these remedial agents are employed are those of over-excitement of the nervous and vascular systems.

Refrigerants are substances calculated to diminish the heat of the body when morbidly increased, and to produce a soothing sensation of coolness. Applied externally as cooling or evaporating lotions to any inflamed part, their operation is easily understood, as they serve merely to reduce the temperature by carrying off the excess of heat. Taken internally, their mode of action is not quite so clear, for though they produce the sensation of coolness, they do not in reality reduce the temperature of the body. The most common refrigerants are vinegar, citric acid, tartaric acid, lemon-juice, the fruit of the orange, nitrate and chlorate of potash, and conserve or confection of dogrose. The principal use of these preparations in practical medicine, is in the treatment of fever and inflammatory affections, in which their direct action on the stomach seems to occasion sympathetically a reduction in the force of the circulation.

Soporifics, a familiar term for the milder agents of the class Narcotics or Sedatives.

Stomachics and *Tonics* form another class of medicines, acting by absorption into the blood, or as vital agents, which cannot be ranked either amongst those that excite action, or those that repress it. The former increase the digestive powers of the stomach, the latter renovate the tone or contractile energies of the muscular fibre. They are slow in their operation, and augment the strength of the body without materially exciting its actions. As these two kinds of medicines are not very distinctly separable, it may be better to enumerate them together. Good nutriment is the most natural and best supporter of the bodily powers; but to effect this purpose, it is necessary that the function of digestion should be in a proper condition. Gentian root, quassia, chamomile, calumba, and canella, assist powerfully this object. Amongst the tonics, Peruvian, cascarilla, cinchona, angostura, and willow barks, the preparations of iron, the sulphuric and nitric acids, are in greatest repute. 'There is no class of remedial agents,' says a high authority, 'which requires more discrimination in their administration than tonics, nor any the injudicious use of which more frequently produces evil consequences. The diseases in which this class of remedial agents are principally employed must manifestly be those of diminished power. In no case, however, should they be prescribed where there is a tendency to irritation or inflammation of the digestive organs, or where the secretions are in a depraved state, without the previous use of means calculated to remove the former or correct the latter; to effect which, the employment of mild purgatives will in most instances be found best adapted. Tonics have a marked action on the various organs of secretion—their effects being to restore them to a healthy state. They are consequently administered with the view of diminishing secretion when it is excessive, or of restoring it when deficient, if either condition depend, as it frequently does, on inertia or want of tone in the secreting organ.' Independently of their tonic properties, some of the remedies contained in this class possess a specific power in ague and other periodical diseases; hence they have been denominated *Febrifuges.*

Few remedial agents are more largely employed at the present day than tonics and stomachics, not only for the purpose of renewing tone and strength where debility actually exists, but with the view of imparting additional vigour—hence the term *corroborants*—where the constitution is in ordinary condition. It is needless to say that the latter is altogether a mistaken notion; and that the best and safest of all corroborants are—proper dietary, clothing, exercise, cleanliness, freedom from harassing cares, and those general regulations insisted upon in the article PRESERVATION OF HEALTH. Were those regulations attended to as they ought to be, the class of remedial agents now under review might safely be swept from the lists of medicinal preparations.

Stimulants is the general term for remedies which excite sensation in the sentient parts, or motion in the muscular parts—in other words, any excitement of the vital energies. It is usual to distinguish them as *general* and *special*, according as they affect the whole system, or exert a peculiar influence on individual

organs or on the system generally. 'It is difficult, however, to define,' says Neligan—whose account of this class we shall adopt—'what is understood in the practice of medicine by the term Stimulant, excitement of the vital energies being produced by such different means under different circumstances. With no class of remedies, therefore, is it more necessary to bear in mind the truth of the maxim, that medicines act merely *relatively*. In their mode of action when administered internally, General Stimulants resemble in some respects Tonics; thus, immediately after their administration, a feeling of increased tone or power is produced, which, however, is not permanent, but is almost invariably followed by a corresponding depression of vital power; their effects also are more immediate, and more manifestly perceived by the senses, than those of Tonics. Many of them are also closely allied to Narcotics; for example, alcohol and the ethers, the secondary effect of both of which, particularly if given in large doses, is to produce sleep and coma. This does not, however, appear to be, as with Narcotics, from any direct action on the nervous system, but rather to result from the previous over-excitement of the vital energies. The great number of medicines contained in this class, and the material difference of their action in relation to the particular effects which they produce, preclude the laying down of any general rule for their administration.' The general stimulants usually enumerated are—alcohol, sulphuric ether, preparations of ammonia, camphorated acetic acid, camphor, anise, capsicum, ginger, cardamomum, caraway, cinnamon, oil of cassia, cocculus Indicus, lavender, mint, pepper, nutmegs, oil of turpentine, rosemary, sherry wine; and to these we may add electricity in its various developments.

With regard to Special Stimulants, 'many of them give rise to some alteration, which is not well understood, in the nature or quality of vital action, when they are called *Alteratives;* while others possess a special influence in the treatment of certain diseases, when they are denominated *Specifics*. Many alteratives and specifics have been already described in other classes of medicines, but the articles contained under this head cannot, with a regard to accuracy of arrangement, be included in any of them; inasmuch as the primary influence which some of them exercise on the animal economy has not been satisfactorily ascertained, and others possess a peculiar influence over *certain organs* or *diseases* merely. As examples of the former, we may refer to mercury, iodine, and gold; of the latter, to nux-vomica, cubebs, and copaiba.' The special stimulants commonly enumerated are—iodides and chlorides of gold, bromine, copaiba, cubebs, numerous preparations of mercury, iodine, iodide of potass, and some marine substances containing iodine; as sponge and cod-liver oil.

Under this section we have mentioned the therapeutical use of alcoholic liquors; and as much error seems to prevail on this matter, we shall here present in brief the opinions of Drs Christison, Pereira, Neligan, and other modern authorities. We avoid the testimony of the older medical schools, as having an evident bias to the employment of these agents; as much as we avoid the dogmas of those who would altogether discard them. Alcohol, in all its forms, is a highly valuable therapeutic agent. In moderate doses, properly diluted, it acts as a general stimulant, exciting particularly the vascular and nervous systems; in somewhat larger doses, it produces the well-known effects of intoxication; and in excessive doses, it acts as a powerful narcotic poison, rapidly causing death, preceded by slow pulse, contracted pupils, and coma. This effect is most usually observed when a large quantity of ardent spirits is swallowed at once, as for a wager. As a stimulant, alcohol is employed in medicine to support the vital powers in the advanced stages of fevers, particularly those of a typhoid character; for this purpose, brandy or whisky is usually employed, but wine is generally preferred. It is also often used as a household medicine in flatulent colic, in indigestion, in vomiting, and in fainting; but for these purposes it is a perilous remedy when resorted to frequently, because apt to lead to the vice of habitual over-indulgence. Mere alcohol is seldom used as a diuretic in regular practice; but it is a powerful and familiar remedy of the kind when united with certain essential oils, of which combinations the most esteemed is Hollands. As an external stimulant, it is a common ingredient in lotions for sprains and bruises, for many forms of external inflammations, as erysipelas and erythema, for various skin-diseases, to prevent excoriations in parts exposed to long pressure, and with friction over the region of the heart in syncope and suspended animation. In consequence of its producing cold by evaporation, alcohol is frequently added to cooling and evaporating lotions. Wines, we have said, are also used internally as stimulants, and for this purpose are often better suited than any other alcoholic liquid. Their use is particularly called for in the advanced stages of typhoid fevers, and where delirium is present, with much sinking of the vital powers. They are also given with advantage in convalescence from acute diseases, in chronic debility, especially when it is caused by excessive discharges, in mortification unaccompanied by inflammatory symptoms, and in tetanus or locked-jaw. When any local congestion or inflammation is present, or may be apprehended, the administration of wine in the treatment of disease is for the most part calculated to do mischief. Although sherry is the only wine officinal in the pharmacopœia, port is generally employed in medicine; claret and Madeira are also used. When its greater strength and astringency are not objectionable, port wine is always to be preferred. Madeira and claret are often inadmissible, on account of their acidity; but when this is not the case, the former is well adapted for persons of debilitated or broken-down habits, the latter when the employment of stronger wines might prove injurious. Sherry is chiefly employed in the preparation of medicated wines; but Cape wine, on account of its cheapness, is usually substituted by druggists. In a dietetical view (see BEVERAGES), sherry is the wine in most general use, and the one calculated to agree best with most constitutions.—Such are the opinions of medical authorities with regard to the medicinal or therapeutic uses of alcoholic liquids; and by their enlightened and unbiassed directions, ought unprofessional parties to be implicitly directed. The dietetic, habitual, or conventional employment of these beverages is altogether a different question.

Forms and Modes of Preparation of Medicines.

Some medicines are prepared in a liquid, others in a solid form, according as they may be soluble or insoluble, or according to the state in which it may be desirable to administer them. In general, the more finely a substance can be divided, the more rapidly is it taken up by the system, and the more instantaneous its effect; hence, instead of administering the crude vegetable or mineral, the necessity of preparing infusions, decoctions, tinctures, and the like. Another reason for adopting such preparations is, that the active or medicinal principle of a substance may constitute but a small portion of its bulk; while the greater portion may be of no value whatever, or may be even positively detrimental.

Infusions of vegetable substances are prepared by pouring boiling water upon the materials in a lightly covered vessel, and allowing it either to cool directly, or to continue at a gentle heat for a few hours; then straining, filtering, and bottling for use. In some cases cold water is preferable. *Decoctions* differ from infusions in being prepared by actual boiling of the substances;

and, if possible, in vessels of glass or earthenware. Decoction is apt to destroy the active principle of many vegetables. *Extracts*, which are much valued in pharmacy, are usually prepared by evaporating, to the consistence of a pill-mass, the expressed juices of plants, or their infusions or decoctions in water or spirits, at a temperature not exceeding 212°, by means of a vapour-bath, or by spontaneous evaporation in shallow vessels exposed to a current of air. *Tinctures* are solutions of vegetable, animal, or mineral substances, in some spirituous fluid—as proof-spirits, rectified spirits, and the like. *Sirups* are intended sometimes to cover the disagreeable taste of drugs, but more generally to preserve them in a convenient state for making mixtures, without the risk of their undergoing decomposition.

When medicines are administered in the solid state, one of the most common forms is that of *Powders*. Being in a state of fine division, powders act with considerable rapidity, and are administered in admixture with some fluid or conserve. *Pills* are regarded as the most convenient of all officinal forms, both for preservation and for administration; but in many instances not the most efficient in point of activity. The active ingredients of the pill are mixed with materials called Excipients, to give it the desired consistence. Bread-crumb is a convenient recipient for immediate use; but to make a pill that will not harden by being kept, conserve of red roses or of hips is considered the best. For preserving pills in a soft and active state, small bottles are much preferable to wooden boxes. According to Dr Christison, pills are usually made too large. 'Five-grain pills often pass through the body apparently but little altered; and it has occurred to me to observe that four colocynth and henbane pills, of one grain each, will operate as effectually as two five-grain pills, and more mildly.' *Lozenges* or *Troches* is another solid form in which drugs are now administered.

Cerates, *Ointments*, and *Liniments*, are preparations for external use, differing chiefly in their consistence—cerates being the firmest, ointments softer, and liniments softer still, or even liquid. As ointments are of use merely to protect wounds from their coverings, from the air, and from filth, the simpler they are the better. The same rules are to be observed in preparing *Plasters*, which have a similar basis spread equally on cloth, leather, or other tissue. *Poultices* are well-known external applications. They are described by Abernethy as of three kinds—the evaporating or local tepid bath, the greasy, and the irritating. The first is thus made: 'Scald out a basin, for you can never make a good poultice unless you have perfectly boiling water; then having put in some hot water, throw in coarsely crumbled bread, and cover it with a plate. When the bread has soaked up as much water as it will imbibe, drain off the remaining water, and there will be left a light pulp. Spread it, a third of an inch thick, on folded linen, and apply it when of the temperature of a warm bath.' The linseed-meal or greasy poultice is, on the same authority, to be made in the following manner: 'Get some linseed powder, not the common stuff, full of grit and sand. Scald out a basin; pour in some perfectly boiling water; throw in the powder, stir it round with a stick, till well incorporated; add a little more water, and a little more meal; stir again, and when it is about two-thirds of the consistence you wish it to be, beat it up with the blade of a knife till all the lumps are removed. Then take it out, lay it on a piece of soft linen, spread it the fourth of an inch thick, and as wide as will cover the whole inflamed part; put a bit of hog's-lard in the centre of it, and when it begins to melt, draw the edge of the knife lightly over, and grease the surface of the poultice.' The irritating poultice to be used in cases where a blister is unnecessary or inconvenient, is made simply of mustard and water, mixed as if for the dinner-table, and put within the folds of a piece of fine muslin, so that only the watery part, oozing through, touches the skin.

Mixtures and *Emulsions* are extempore preparations, of such strength, consistence, or quality, as each particular case may demand. The same may be said of *Fomentations*, which are warm fluids applied to the skin; and of *Lotions*, or washes, which are similarly applied either cold or warm. *Enemas*, or *Clysters*, are drugs administered in the form of injections; they vary in composition and volume according to the object to be effected.

In whatever form medicinal preparations may be administered, the quantity is invariably regulated by weight or by measure. Though differing in nomenclature and mode of subdivision, both of these are based on the imperial standard of the country. Thus the imperial pound Troy is divided into ounces, drachms, scruples, and grains; and the imperial gallon into pints, fluid ounces, fluid drachms, and minims. In detail—12 ounces make 1 pound, 8 drachms 1 ounce, 3 scruples 1 drachm, and 20 grains 1 scruple. Again, 8 pints make 1 gallon, 20 fluid ounces 1 pint, 8 fluid drachms 1 fluid ounce, and 60 minims 1 fluid drachm. The different denominations of weights and measures are denoted in the language of prescriptions by the following signs: Pound, ℔; ounce, ℥; drachm, ʒ; scruple, ℈; grain, gr.; Gallon, C; pint, O; fluid ounce, fl℥; fluid drachm, flʒ; and minim, m. Medical prescriptions are generally written in Latin, which, conjoined with these signs, Roman numerals, and a large amount of contractions, gives them a very formidable and mysterious aspect. Thus, ℞ (*Recipe*) *Nitratis Potassae* gr. xv.; *Aquae destillatae* fl℥iss; *Syrupi Limonum* flʒij. *M* (*Misce*). *Fiat haustus, ter in die sumendus*, is but the technical form of ordering the patient to 'Take fifteen grains of the nitrate of potass; one and a half fluid ounces of distilled water; and two fluid drachms of sirup of lemon. To mingle and form a drink of them, and take it three times a day.' Further, each university of importance has a list of medicinal preparations drawn up for the guidance of its own members and pupils, and this list is termed its *Pharmacopœia:* with the enumeration is given a full account of the processes by which the various substances are prepared for use. Thus London, Edinburgh, and Dublin have their respective Pharmacopœias; differing occasionally in particulars, but rarely or ever in essentials.

Medicine-taking.

The medicines most commonly employed at the present day for the alleviation or cure of disease have been now enumerated, in an arrangement which may shew their several properties and modes of operation. The information will have the effect, we humbly imagine, of dissipating some portion of that veil of mysticism which envelops the art of medicine, and of shewing what are the rational objects to be expected from the action of drugs upon the animal frame. There are at present two injurious opinions prevalent in the world on this subject, both of which are entertained alike by the ignorant and by the enlightened, and which are equally at variance with the truth, and noxious in their consequences. The first of these opinions is, that the science of medicine is from beginning to end a deception; that medical men are as much in the dark as their patients with regard to the cause and nature of disease, and are consequently quite unable to provide a remedy. Enlightened men are more liable, upon the whole, than the ignorant to imbibe this feeling of distrust. One of the most elegant writers of the day, for example, bitterly and satirically defines medicine to be 'the practice of pouring substances of which nothing is known, into bodies of which still less is known.' An opinion of this kind of course leads the person who holds it to regard the regular physician and the empiric as upon a level, and to look upon the prescriptions of the one as equally

contemptible, or, in other words, equally valuable, with those of the other. Those who hold this opinion, and indulge in sneers at what they do not comprehend, lose sight of the fact, that medicine is only one of many progressive sciences—its data being of a varying character, its conclusions must necessarily vary. The second opinion, which we alluded to as being prevalent in the world, is directly the reverse of the first, and is more common amongst the ignorant than amongst the intelligent part of mankind. It is a belief in the boundless powers of medicine, which leads those who entertain it to treat their bodies as if these had been designed by nature merely as receptacles for drugs. This opinion tends also to render those who hold it a prey to every successive nostrum that knavery and quackery can invent. It is based upon the very same foundation as the opposite opinion—namely, the mysticism that obscures the true objects and powers of medicine, for with some minds, whatever is dark and mysterious, becomes invested with supernatural qualities.

The persons who thus consider the art of medicine as unlimited in its powers, and believe that the body can never be in a proper state unless under the influence of some drug, are generally those who pore over all the medical books they can get hold of, and imagine themselves successively to be the subjects of every disease described. Finding an enumeration of remedies accompanying the descriptions of diseases in the books they read, they try medicine after medicine, till they impair their bodily powers, and create diseases where none originally existed. Sometimes this method of self-drugging and self-killing is varied by a mania, equally destructive, that leads them to the trial and use of all the pretended remedies which ignorant empirics foist so unremittingly on the world. Those knavish gentlemen, generally termed *quacks*, know thoroughly the points upon which the success of their gulling depends, and accordingly publish imaginary letters addressed to themselves, descriptive of cases in which their invaluable medicine, in the form of drops, pills, powders, or elixirs, 'has been of incalculable service.' These cases embrace every disease, and every symptom of disease, under the sun; and the infatuated beings who read and trust to them find always some fictitious case of cure, which appears to resemble their own complaint, and accordingly are deceived into the purchase of the 'invaluable medicine.' Were these quackeries simply impositions upon the credulous, the evil would not be so great; but exceedingly few of them have so much merit as to be innoxious. On the contrary, the records of the criminal courts tell a fearful tale of credulity, punished in many instances by death.

It is not with a view to increase the number of those who tamper, in the way described, with medicines that the preceding pages have been written. If such should be the consequence of the information they contain, no one would deplore it more sincerely than ourselves; but we confidently hope that, as far as their humble influence extends, the result will be very different. Those to whom the action of medicines on the system is a mystery, may fly to the quack for a nostrum, or try to discover one themselves; but those who have given the subject so much attention as to be aware that the action of medicinal substances on the body is as varied as the disorders which they are applied to remedy, and at the same time to a great extent demonstrable and intelligible—those who are possessed of this knowledge will scout the idea of a universal panacea, and despise the quack and his nostrums, while at the same time their confidence in the man who has devoted his days to the consideration and relief of disease will be increased tenfold, since they are assured that his objects and his plans are consonant to the soundest principles of true science, of reason, and of common sense.

We have just one word of advice to give in conclusion, and it is this: When any one feels himself afflicted with a complaint anyway beyond a very slight indisposition, let him at once, and without a moment's delay, send for a regular and skilful medical attendant, to whom let him communicate freely the state of his feelings, as well as what has been his previous course of life. The grand error in most people consists in 'putting off sending for the doctor' till it be too late.

Dr Combe says: 'Many mothers are continually administering medicines of one kind or another, and thereby deranging instead of promoting the healthy operation of the infant system. Instead of looking upon the animal economy as a mechanism constituted to work well under certain conditions, and having, in virtue of that constitution, a natural tendency to rectify any temporary aberrations under which it may suffer, provided the requisite conditions of action be fulfilled, they seem to regard it as a machine acting upon no fixed principles, and requiring now and then to be driven by some foreign impulse in the shape of medicine. Under this impression they are ever on the watch to see what *they can do* to keep it moving; and, altogether distrustful of the sufficiency of the Creator's arrangements, they no sooner observe a symptom, than they are ready with a remedy. Such persons never stop to inquire what the *cause* is—whether it has been, or can be, removed—or whether its removal will not of itself be sufficient to restore health. They jump at once to the fact that disease is there, and to a remedy for that fact. If the child is convulsed, they do not inquire whether the convulsions proceed from teething, indigestion, or worms, but forthwith administer a remedy *to check the convulsions;* and very probably the one used is inapplicable to the individual case; and both the disease and the cause being, in consequence, left in full operation, instead of being removed, the danger is increased. . . . . I have no hesitation in expressing my conviction that a child can encounter few greater dangers than that of being subjected to the discipline of a medicine-giving mother or nurse; and wherever a mother of a family is observed to be ready with the use of calomel, cordials, anodynes, and other active drugs, the chances are, that one-half of her children will be found to have passed to another world.'

SURGERY.

Nature, says Mr Lawrence, 'has connected the outside and the inside of the body so closely, that we can hardly say where one ends and the other begins.' It is therefore impossible exactly to define the boundary-line between medicine and surgery. Suffice it to say, that surgical diseases generally are those situated in parts of the body accessible to touch and to the direct application of remedies. Surgery, therefore, includes the treatment of the various injuries to which our bodies are constantly exposed in the daily occupations of life or from accidental circumstances. As most of those injuries occur when least expected, and when professional assistance is difficult to obtain, it is the duty of all men to inform themselves of the general principles upon which relief is afforded in cases of accident. We intend, therefore, to give a few leading directions suitable for cases of emergency—not by any means with the view of superseding the legitimate practitioner, but that in the interval which necessarily must elapse between the occurrence of the accident and the arrival of surgical assistance, the sufferer may be intelligently cared for; and that the surgeon may not, as too often happens, find his skill of no avail on his arrival, or have to use it to remedy the hurtful effects of ignorant interference. In country-houses, a medicine-chest should be kept, which may be obtained from any qualified druggist, and should contain some laudanum, chloroform, sal-volatile, quinine, and some of the simpler purgative medicines;

also some styptics, as gallic acid. Other drugs may be added as recommended by the medical practitioner of the neighbourhood. There should be a pair of scales for weighing out doses, and a graduated glass measure for fluids.

In the way of surgical appliances, there should be at hand some adhesive plaster, lint, simple spermaceti ointment, and a spatula for spreading it with; some roller bandages, three inches wide and eight yards long; scissors, a lancet, and a few surgical needles, which should be kept threaded with white silk, well waxed; a pair of forceps for taking up, and some fine twine or silk for tying, arteries.

BLEEDING.

Discharges of blood take place occasionally from nearly all the apertures of the body; and as they are frequently critical, or, in other words, the means employed by nature to relieve some local congestion, should not be checked, unless they threaten to induce a dangerous degree of exhaustion.

Bleeding from the nose may generally be checked by cold, by snuffing up powdered tannin, or, if that is not sufficient, by stopping the nostrils with little plugs of lint. It must be borne in mind, however, that the nostrils open behind into the upper part of the gullet, and that the blood may flow freely down the latter, though no longer appearing externally. If this be the case, the posterior nostrils, as they are called, must be plugged by a surgeon. If a person appears faint from loss of blood, he should be laid flat on his back; and if he can swallow, some stimulant—as wine or brandy—given him in small quantities. This should be done at once, as persons who have lost much blood are very liable to die from a sudden faintness or syncope.

Bleeding from wounds is either a general oozing from the surface, or from veins, when the blood flows in a continuous stream of a dark colour, or from arteries, when it is of a bright scarlet colour, and issues from the vessel in jerks. The oozing and venous bleeding will generally stop on the application of cold, pressure, or exposure to the air. The blood should not be allowed to coagulate in a wound, as the clot acts like a warm wet sponge, and encourages bleeding. Cut ends of arteries may be distinguished, by their remaining open, from those of veins, which collapse. An artery should be seized with the forceps, gently drawn out from the surrounding tissue, and tied with fine silk or twine; one end of the ligature should be cut away close to the knot, the other left in the wound, from which it may be gently pulled in two or three days.

If the artery be very small, a twist with the forceps may suffice, instead of the ligature; but if there be any doubt, the latter should be preferred. Veins should not be tied, as the inflammation of their coats necessarily produced by the ligature might be extremely hazardous to life. If the ends of the vessel are not easily reached, no attempt should be made to secure them till the arrival of a surgeon. In the meanwhile, the wound, or the main artery of the part, should be compressed; and it should be remembered that very slight pressure is sufficient, if properly applied; whereas, if exerted too energetically, the strongest thumb is soon wearied and useless. If there is a wound in the armpit, the handle of a door-key, with a turn of some cloth round it, may be pressed downward behind and above the middle of the collar-bone, so as to press the subclavian artery against the first rib. The thumb is scarcely powerful enough in such a case.

If the bleeding be very profuse, and attendance scanty, a tourniquet may be extemporised thus: A handkerchief should be passed a few times round the limb above the wound, and if the situation of the main artery is known, a pretty hard pad should be adjusted over it; the handkerchief should then be twisted sufficiently tight by means of a stick inserted between two of its turns. Direct pressure upon the artery, when efficiently applied, is, however, generally preferable to the tourniquet, which is very hurtful to the limb if left on too long.

Wounds are generally divided into cuts or *incised* wounds, and deep narrow stabs or *punctured* wounds, inflicted with sharp weapons; and into *contused* and *lacerated* wounds, when the injury has been accompanied, owing to the bluntness or roughness of the weapon, with bruising and tearing.

In an ordinary cut, the best practice is to bring the edges together, and wrap a piece of dry lint round the part. If there is any difficulty in keeping the cut surfaces in apposition, strips of plaster should be placed across the wound at intervals, or a few stitches, also at intervals; at each stitch the thread should be cut, and its ends tied in a common knot: this is called the *interrupted suture*, and is most commonly in use among surgeons. If recently cut surfaces are placed accurately in contact, they will, in all probability, reunite in a few hours by what is called *the first intention*. In wounds of the scalp, the surrounding surface should be shaved, and strapping applied in preference to stitches, as the latter are apt in some patients to induce erysipelatous inflammation. The orifices of punctured wounds should not be closed; and if inflicted with a dirty weapon, a poultice should be applied. Contused and lacerated wounds can hardly be expected to heal without undergoing some previous preparation; the portions of tissue which are much bruised will slough or die and separate; the surface of the wound will then be of a florid red, covered with minute fleshy elevations called *granulations;* these secrete a creamy fluid called *pus*, which protects them from the air, and must not be wiped off the surface of the sore. By degrees these granulations rise to the level of the surrounding skin, and then contract, drawing the margins of the sore nearer each other, and are converted into a tough non-elastic tissue called *cicatrix* or *scar*.

The best dressing for a healing wound is lint soaked in tepid water. If the healing action is languid, some stimulating ingredient may be added, as tincture of myrrh, in the proportion of a drachm to a pint of water; or the famous red lotion, which contains a grain of sulphate of zinc to an ounce of distilled water.

BURNS AND SCALDS.

When heat is applied to the surface of the body, either through a solid or fluid medium, the injuries produced will be almost alike, and their severity in proportion to the amount of caloric applied. Therefore, the directions for the treatment of scalds will be applicable also to burns; and those injuries may be divided into three classes:—1. Burns resulting in simple redness of the skin; 2. Burns resulting in vesication or blistering; 3. Burns resulting in sloughing, or death of the part. The first object, after the accident has occurred, is to relieve the suffering; and cold applied either in the form of ice or water seems in most cases to have almost a specific power in allaying pain and checking the advance of inflammation. In other cases, moderate warmth is found more efficacious, and we must be guided mainly by the sensations of the sufferer as to which of these remedies we make use of. In very severe cases, opium or chloroform may be employed. But if the injury the body has received be very serious, the patient complains less of pain than of cold; he shivers, is much depressed, and must be well supplied with stimulants to prevent his dying from shock.

The best local application is the Carron-oil, which derives its name from the famous ironworks, where it has been used for many years. It consists of equal parts of olive-oil and lime-water, and should be applied on linen rags or cotton-wool. Blisters may be pricked, and the contained serum allowed to trickle away, but on

no account is the raised skin to be removed. The dressings should not be changed oftener than cleanliness requires; and as each portion of the old dressing is removed, it must at once be replaced with fresh, so that as little exposure as possible of the burnt surface may take place. The main principle of treatment is exclusion of the air from the injured part; and so long as this is effected, it matters but little what remedial agent is employed. Great care must be taken in the treatment of a sore resulting from a burn, that the contraction of the scar does not cause distortion of the neighbouring parts.

When the clothes catch fire, the person should lie down on the floor, and roll herself, or be rolled, in the rug, table-cover, or anything sufficiently voluminous to stifle the flames; and afterwards the clothes, especially stockings, should be removed with great care, lest the cuticle should separate with them, which would materially increase the sufferings of the patient.

Extensive scalds or burns are very fatal to young children; and it must be remembered that their skin is more susceptible to external impressions, and will suffer from a degree of heat innocuous to an adult. Infants have frequently been scalded to death in too hot baths, or by too hot fomentations.

The principles of treatment for burns produced by the contact of chemical agents to the skin, are the same as those for burns by fire.

The symptoms produced by intense cold have a curious resemblance to those from intense heat. In this country, the most common effect is an inflammation of the skin called a *chilblain*. Chilblains are most commonly induced by sudden alternations of temperature, as when a person holds his cold toes too close to the fire. The treatment must depend on the severity of the inflammation; and after the latter has subsided, gentle stimulating applications, such as the soap liniment, or a liniment made by adding one ounce of mustard to a pint of turpentine; but care must be taken not to cause ulceration, as the sores arising under such circumstances are exceedingly troublesome and difficult to heal. When a part or the whole of the body has been exposed to severe cold, the surface appears pallid or yellowish white, and is insensible to touch. The living principle is lessened and feeble, and any sudden change of temperature would destroy the little that remains; so life must, as it were, be coaxed back by the gradual application of warmth. The part or whole body must be rubbed with snow or cold water, and as vitality returns, the cold media be gradually laid aside, and some warm tea, or wine and water, given internally.

INJURIES TO JOINTS.

The ends of bones entering into the formation of joints are covered with smooth gristle or cartilage, so that their motions upon each other may be smooth and unimpeded; and to insure this object, they have between them a bag of a thin tissue, called synovial membrane, which secretes synovia, or joint-oil, to lubricate the cartilaginous surfaces. They are bound to each other by strong white fibrous tissue, adjusted so as to keep those surfaces in their proper relations to each other, without impeding their movements. These fibrous bands are the ligaments.

A sprain consists in a wrench or strain of these ligaments. The synovial membrane which is in contact with them participates in the injury, and immediately inflaming, pours its fluid into the joint, causing swelling; which, confined by the surrounding fibrous structures, gives rise to great pain and constitutional disturbance. These symptoms vary in proportion to the severity of the injury. Rest and fomentations of hot water to the joint, and a dose of Dover's powder, followed by a purge, are usually sufficient. If the inflammation be very acute, and there is headache with quick pulse, half-a-dozen leeches should be applied, three on each side of the joint, in addition to the fomentations. No liniments should be made use of till the acute symptoms have passed away, when the soap liniment—the opodeldoc of the shops—will be found very efficacious.

A dislocation is when the surfaces of the bones forming a joint are displaced, and have no longer their proper relations to each other. The appearance of the joint is immediately altered, its movements limited, and accompanied by intense pain. The displacement may be partial or complete; it may be obvious to the most ignorant observer, or so obscure as to puzzle the most experienced surgeon. Soon after the occurrence of the injury, swelling takes place, accompanied by an increase of pain, and the constitutional symptoms of inflammation soon make their appearance. After the swelling has come on, it is generally very difficult to detect the nature of the injury, as the prominent points of bone can no longer be traced; therefore the sooner the surgeon is summoned the better, as the future usefulness of the limb will depend upon his treatment of it; and if dislocation has taken place, the longer its reduction is delayed, the more difficult will it be.

Fractures are of three kinds—*simple*, when the bone is broken; *compound*, when it is broken and a wound in the skin communicates with the fracture; *comminuted*, when it is broken into several small pieces. The symptoms are, great mobility, and a grating feeling when the bones are rubbed. Directly a bone is broken, the muscles contracting, displace the fragments. Here, as in dislocation, the chief obstacle to reduction is the muscular resistance. The surgeon must place the limb in the position which relaxes the muscles acting on the furthest fragment, and by gentle extension, bring the broken ends again in apposition; then he must fix them by adjusting some mechanical contrivance, as a splint of wood, pasteboard, or gutta-percha, properly padded, so as not to excoriate the skin, and fasten it to the limb with a few turns of a bandage. After a bone is once set, it should not be disturbed, but it is nevertheless desirable to ascertain the condition of the parts; therefore the bandage ought not to be carried over the seat of fracture; indeed, the less there is on the limb the better.

The symptoms of *fractured ribs* are generally to be gathered more from the feelings of the patient than from any direct evidence from grating or loss of form. On taking a deep inspiration, the patient feels acute pain at the seat of fracture. It is not of much consequence ascertaining the exact number of ribs fractured, and, moreover, the examination is extremely painful. A broad bandage should be rolled tightly round the chest, which, by fixing the ribs, and preventing the contractions of the muscles which lie between them, will give the patient much relief. The constitutional treatment must be to prevent the occurrence of inflammation within the chest. If the sharp broken end of a rib has been forced in, so as to tear the lung, the air is forced into the cellular tissue under the skin, and produces the condition called *emphysema*, which may be recognised by the puffiness and crackling upon pressure.

If the broken ends of a bone be kept at rest and in apposition, a few hours after the injury, inflammation occurs, and lymph is poured out around and between them, which becomes solid: it is called *provisional callus*, and forms a sort of natural splint. The substance interposed between the fractured ends becomes gradually converted into bone, and remains firm and strong, while the provisional callus, which forms an unsightly swelling, is absorbed, and the bone regains its former outline. In moving a fractured limb, it must be borne in mind that the sharp ends of the bones are lying among important soft parts, which may be easily lacerated by them; so the limb should be kept perfectly steady, and the patient moved with the greatest care. If a surgeon's advice can be obtained, no attempt

should be made at examination of the limb till his arrival; and unless absolutely necessary, no purgative medicines should be given, as they necessitate movement of the body, and consequently of the fractured leg; unless, indeed, the limb is swung—an improvement in modern surgery which cannot be too much recommended.

Fracture of the skull is generally very serious; frequently, though there is no fracture visible, there may be one through the base of the skull, which is almost always fatal, owing to the rupture of the large veins which take the blood back from the brain. These injuries are accompanied by symptoms classed under the heads of concussion and compression of the brain. Concussion, or stunning, occurs immediately on the receipt of the injury, and may be instantly fatal; or the patient, after lying a variable time, with his pupils often of different sizes, his skin cold, and his pulse weak and irregular, may recover consciousness, and be himself again; or gradually, owing to bleeding taking place within the skull, exhibit the terrible symptoms of compression of the brain, which are dilated pupils, unaffected by the brightest light, snoring, complete insensibility, and the cheeks flapping out at expiration. So complete is the paralysis, that the bladder no longer contracts to expel the urine which accumulates in it, and the muscles of the lower end of the bowel allow of the involuntary escape of its contents. If these symptoms depend upon the pressure of a piece of bone driven in upon the brain, the surgeon may elevate it by the operation of trephining; but if they depend upon effused blood, the patients rarely recover: children, however, rally after the most severe injuries, their elastic cranial bones gradually regaining their proper positions. In concussion, nothing should be done except removing the neckcloth, and leaving the patient *perfectly quiet;* and protecting him from the application of popular remedies—such as bleeding, pungent salts to the nose, or the administration of stimulants. Even after apparent recovery, careful watching is necessary, as it is for some days uncertain whether serious symptoms may not make their appearance. In accidents to the head, more perhaps than in any others, is passive obedience to the surgeon's directions absolutely necessary.

The symptoms produced by fractured spine vary according to the situation of the fracture. All the body below the injury, if the spinal marrow has been compressed, as generally happens, is paralysed; and if it be situated about the third vertebra in the neck, between the brain and the origin of the *phrenic* nerve, which supplies the diaphragm, the great muscle of respiration, death ensues very soon from suffocation. The attendants ought to remember that the paralysed parts are very susceptible of injury from heat, which to the healthy hand does not seem excessive; and, above all, should take care that the patient does not have the loathsome addition of a sore back to his other misfortunes. This depends upon the attendants, who must keep the sheets smooth, sponge the back with spirits and water, cover any inflamed spot with amadou (German tinder) or spongiopiline, and, if necessary, procure a water-bed.

POISONS.

By the word poisons, we mean any substance which, when applied to the body either externally or internally, has the power of producing effects deleterious to the animal economy. If a poison be swallowed, and we cannot get rid of it by emetics or the stomach-pump, we are obliged to administer other substances, which, by combining with the poison, may so alter its chemical properties as to render it innocuous. These latter remedies are called antidotes. We give a list of some of the most common poisons, arranged alphabetically for facility of reference.

The following extracts are made in a great measure from Thomson's *Conspectus of the Pharmacopœia:*

ACIDS.

Symptoms.—Great heat; burning pain in stomach; convulsions; death.

Antidote.—Magnesia; soap in water; after which the stomach should be emptied by the stomach-pump, or an emetic.

ARSENIC—A corrosive mineral poison.

Symptoms.—Metallic taste; spitting, nausea, and vomiting, which is occasionally mixed with blood; fainting and great heat at the throat; severe gripings, purging, and tenesmus, the stools being deep green or black, and horribly offensive; the urine scanty, red, and often bloody; palpitation of the heart; cold sweats; itching and swelling of the body; prostration of strength; paralysis of the feet and hands; delirium; convulsions; death.

Treatment.—Evacuate the stomach by the stomach-pump, using lime-water; administer large draughts of tepid sugar and water, chalk and water, or lime-water; avoid the use of alkalies, but administer charcoal and hydratic sesquioxide of iron; bleed freely; take a tepid bath, and use narcotics. If the fatal symptoms be averted, let the patient for a long time subsist wholly on farinaceous food, milk, and demulcents.

BLISTERING FLIES—An acrid animal poison.

Symptoms.—Nausea, vomiting, and purging; bloody and purulent matter; irritation of the bladder; pulse quick. If these symptoms be not soon relieved, they are followed by convulsions, tetanus, delirium, syncope, and death.

Treatment.—Bleeding; warm bath; opiate frictions; and clysters of mutton-broth and opium. Camphor applied both internally and externally.

CORROSIVE SUBLIMATE—A corrosive metallic poison.

Symptoms.—An acrid metallic taste, burning throat, salivation, nausea, and vomiting of blood; diarrhœa; tenesmus; the pulse small, quick, and hard; faintings; debility; difficult respiration; cold sweats; cramps of all the members; convulsions; and death.

Treatment.—White of egg, diluted in water, given in large doses; a mixture of soap and gluten of white flour; bleeding; warm bath; and to subsist upon broth, milk, and demulcent fluids entirely.

DEADLY NIGHTSHADE—An acro-narcotic vegetable poison.

Symptoms.—A sense of great dryness, and constriction of the pharynx; sickness; dilated pupils; dim sight; laughter; delirium; redness of the face; convulsions. The stomach becomes so paralysed, that vomiting cannot be produced, and death follows.

Treatment.—Give emetics of sulphate of zinc or copper; evacuate the bowels by purgatives and clysters; give large doses of vinegar and water; and after vomiting, strong coffee proves very efficacious.

FUNGUSES—Poisonous mushrooms, acro-narcotic vegetable poisons.

Symptoms.—Nausea, vomiting, and purging; cramp of the lower extremities; convulsions; an unquenchable thirst; delirium; coma; and death. The intellect remains entire to the last moment of life.

Treatment.—Three or four grains of tartar emetic; castor-oil; the lancet may be required. After the stomach is emptied, give small doses of ether in mucilage, diluted with vinegar. The debility must be treated with cinchona and other tonics, if a fatal issue is averted.

HEMLOCK—A narcotic vegetable poison.

Symptoms.—Sickness; difficulty of respiration; great anxiety; vertigo; delirium, which often rises to maniacal frenzy; dilatation of the pupils; stupor; trismus; convulsions; and death.

Treatment.—Evacuate the stomach by a scruple of sulphate of zinc, dissolved in an ounce of water; the affusion of cold water on the head; bleed freely; and administer vinegar and water, or any other acidulous liquid.

HENBANE—A narcotic vegetable poison.

Symptoms.—Sickness, stupor, dimness of sight, and delirium, followed by coma; dilatation of the pupils; the pulse is at first hard, but becomes gradually weaker and tremulous; petechiæ often make their appearance as the forerunners of death.

Treatment.—Evacuate the stomach by a powerful emetic; administer vinegar and acidulous drinks; but if the poison has already entered the system, bleed and purge frequently to stop inflammatory symptoms.

MONKSHOOD—An acro-narcotic poison.

Symptoms.—Vomiting; heat in the throat; attempts to swallow; perfect consciousness until just before death; debility; disordered vision; contracted pupil; bloody stools; collapse; generally no convulsions.

Treatment.—Evacuate the substance from the stomach, then administer freely acidulous fluids and cordials. External warmth; sinapisms.

MORPHIA.

Symptoms.—The acetate and hydrochlorate of morphia, in doses of three to six grains, cause headache, dimness of sight, vomiting, diarrhœa, costiveness, itching of skin, profuse sweats, convulsions, sometimes of an epileptic character. The acetate, in particular, causes tetanic twitching, generally terminating in death.

Treatment.—The same as in opium.

NUX-VOMICA (*Strychnia*)—An acro-narcotic vegetable poison.

Symptoms.—Sensation of inebriety; vertigo; tetanic twitchings; rigidity of the limbs and arms; extreme difficulty of respiration, with excruciating pain under the xiphoid cartilage; asphyxia, and death.

Treatment.—Evacuate the stomach and bowels, and then dilute freely with vinegar and water, and any other acidulous drinks.

OPIUM—A narcotic vegetable poison.

Symptoms.—Drowsiness and stupor, followed by delirium, pallid countenance, sighing, deep stertorous breathing, cold sweats, coma, and death.

Treatment.—Use the stomach-pump, or an emetic consisting of ʒss of zinc, and vomiting should be kept up by irritating the throat; use an astringent infusion instead of water with the stomach-pump. Give large draughts of vinegar and water, keeping awake the sufferer; a tepid bath; and dash cold water on the head, to rouse the sensibility.

OXALIC ACID—A corrosive poison.

Symptoms.—Burning pain in the stomach, nausea, and severe but ineffectual efforts to vomit; great dilatation of the pupils; vertigo, convulsions, and death.

Treatment.—Administer, as soon as possible, a mixture of chalk and water, then evacuate the oxalate of lime thus formed, by exciting vomiting, by copious dilution, and irritating the fauces.

PHOSPHORUS—A corrosive poison.

Symptoms.—Phosphorus, taken even in moderate doses, produces immediate death; and as it has been exhibited as a remedy, in this manner it may prove poisonous. The symptoms are violent pain of the stomach, with a hot taste in the mouth; great excitement of the arterial system, convulsions, followed by death.

Treatment.—Dilute largely, so as to fill the stomach with liquid, by which vomiting is produced without increasing the irritation of the viscus. Magnesia mixed with the fluid exhibited, is useful by neutralising phosphoric acid, which is formed in these cases.

PRUSSIC ACID—A sedative poison.

Symptoms.—If the dose is large, death is the immediate result; but if it does not exceed ten to twenty drops, it is followed by stupor, nausea, faintness, loss of sight, difficult respiration, dilated pupils, small pulse, syncope, terminating in death.

Treatment.—Chlorine water in doses of fʒij in f℥j of water; chlorine, largely diluted with air, inhaled; hot brandy and water, or camphor mixture, combined with liquid ammonia; oil of turpentine; cold affusion should be applied, and artificial respiration.

RATTLESNAKE POISON.

Symptoms.—Quick pulse; impeded respiration; sudden depression of strength in the wounded limb, extending over the whole body; convulsions; death. The wound becomes speedily gangrenous.

Treatment.—A ligature above the bitten part; suction of the wound; apply cupping-glasses; cauterise by hot irons or caustics. Administer internally eau de luce, ammonia, and olive-oil.

SULPHURIC ACID—A corrosive mineral poison.

Symptoms.—Austere taste in the mouth; heat in the throat and stomach; nausea; vomiting; horrible breath; the matter vomited tinged with both arterial and venous blood, and air-bubbles form on the spot if it fall upon marble or chalk; inflammation, and a cough resembling croup; concentrated irregular pulse; anxiety; convulsions of the face and lips. The intellect remains clear to the last moment of life.

Treatment.—Dilute instantly with milk mixed with calcined magnesia or soap, or fixed alkalies; and treat the secondary symptoms the same as in inflammation of the intestines.

TARTARIC ACID—A corrosive poison.

Symptoms.—Nearly the same as in poisoning by oxalic acid, but less severe.

Treatment.—Solutions of the alkalies, or chalk and water, and the secondary symptoms by bleeding.

Tartar Emetic—A corrosive mineral poison.

Symptoms.—Nausea; vomiting; hiccough; burning in the pit of the stomach; small, hard pulse; syncope; difficult respiration; vertigo; insensibility to external stimulants; cramps; prostration of strength; death.

Treatment.—Dilute with tepid infusion of galls, and evacuate by the stomach-pump; give large doses of yellow cinchona bark, to excite vomiting by their bulk.

Tobacco—A narcotic vegetable poison.

Symptoms.—Nausea; vomiting; headache; inebriety; sinking strength; cold sweats; tremor; convulsions; death.

Treatment.—Evacuate by three or four grains of tartar emetic; irritate the throat; give astringent fluids, tincture of yellow cinchona bark, or tincture of galls. Brandy, camphor, and cordials are useful.

Verdigris—A corrosive metallic poison.

Symptoms.—Dry, parched tongue; nausea; constant spitting; efforts to vomit; dragging at stomach; colic; griping; black stools; pulse hard and irregular; thirst; anxiety; cold sweats; cramps; convulsions, and death.

Treatment.—Large doses of syrup or sugar, albumen, and water, until the stomach is evacuated; then continue the albumen in moderate doses, combating inflammatory symptoms by bleeding.

DISEASES OF THE EYE.

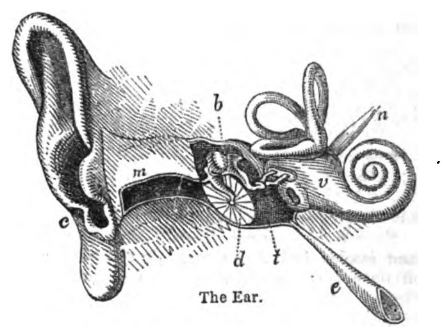
The eye is made up of so many different parts, each of which is subject to its own special maladies, that many surgeons, in different countries, devote themselves entirely to the study and practice of what is termed ophthalmic surgery. We do not intend entering fully into the subject, because its very nomenclature would be incomprehensible to the general reader; and the eye is of too great importance to be treated, except in simple cases, or under very peculiar circumstances, by an amateur practitioner. The most common affection of the eye is inflammation of the membrane which lines the insides of the eyelids and the front of the eyeball, the conjunctiva. Inflammation of this membrane is called *ophthalmia*. The symptoms of the simple form which is produced by some irritation either local or constitutional, or exposure to sudden changes of temperature, are, general redness of the eye, and fulness of the vessels; the patient becomes conscious that he *has* an eye, with a feeling as if dust were in it, and a strong inclination to rub the lids against the eyeball; there is also more or less intolerance of light. If these symptoms continue, there is a slight discharge of matter, and perhaps headache, with some degree of fever. The treatment must be varied according to the patient. If he be stout, and previously healthy, the bowels should be cleared with a dose of calomel, followed by a purgative draught; the eyes bathed with hot water, and shaded from the light: in severe cases, two or three leeches may be put upon the lower lid. If the patient be of a delicate constitution, all lowering remedies should be avoided. In both cases, after the acute stage has passed, astringent lotions may be used, and a few drops of a solution of nitrate of silver, or sulphate of copper, or sulphate of zinc, from the strength of gr. ij to f℥j of water upwards, may be put into the eye twice or thrice a day. When any foreign body finds its way between the eyelids, search ought to be made for it by inverting the lids; if it be sticking in the transparent cornea or the white of the eye, it must be picked out. If it be lime or mortar, the eye must be washed out as thoroughly as possible with vinegar and water, and a drop or two of castor-oil should be put into it. An overflow of tears may be caused by the passages through which they ought to flow into the nose being obstructed.

Squinting, or *strabismus*, is when the two eyes do not act in unison. Whatever may be the primary cause of this deformity, the agents are one or more of the muscles which move the eyeball. The treatment of squint ought to be, rest of the squinting eye, which is generally weaker than the other, and such remedies as tend to strengthen the constitution. When it appears evident that the squint is of a nature likely to be permanent, a surgeon should be employed to divide the faulty muscle, an operation easily accomplished, and one which ought not to be too long delayed, as the squinting eye, not being used so much as the sound one, becomes of a different focus, and otherwise less useful. Temporary squinting may be produced in children by irritation of the bowels from worms, or by teething.

A black eye, or ecchymosis from a blow on the eye, is merely inconvenient. If the effusion is great, it may be punctured, and allowed to bleed; but the only remedy is patience and fomentations with hot water.

THE EAR.

The ear is divided by anatomists into an external, middle, and internal ear. Each of these parts has its



The Ear.

own special diseases; and aural surgery has become of late years almost as complicated a subject as the surgery of the eye. We shall only allude to some of the commoner maladies; and we would warn our readers to beware of the many remedies which go under the name of 'cures for deafness,' and which can only benefit those who sell them. Some forms of deafness are very insidious in the outset, and many men continue to trifle with them until the sense of hearing is irrecoverably lost. The canal or meatus, marked *m* in diagram, which opens externally is about an inch long, and is formed partly of cartilage and partly of bone; the outer part is covered with small hairs, and has numerous sebaceous glands. The inner part has numerous ceruminous or wax-forming glands; this is the narrowest part of the passage. Accumulations of wax may be partially removed with a scoop, and then the passages should be syringed out with *clean warm water*. It is well, the night before syringing, to drop a little warm olive-oil into the ear. *Discharge of matter* from the ear may be the symptom of various diseases of the organ; it is most common in children during dentition, and it sometimes follows scarlet fever. A glance at the accompanying drawing will assist the reader to understand the discharge from the middle ear or tympanum, marked *b*, *d*, *t*, which is the most serious case, and is that kind usually following scarlet fever. It may be set up by inflammation extending from the throat up the Eustachian tube, *e* in diagram, which becomes closed by its thickened lining membrane. The matter secreted then accumulates in the cavity of the tympanum or drum of the ear, bursts through

the membrana tympani, *d*, and escapes externally at *c*. This may be caused by diseased bone in the ear, and sometimes is the result of meddlesome and ignorant doctoring. When a person, after an attack of fever, is about to become the subject of the last-described serious malady, he feels the pain which was previously confined to the throat extending into the ear. It becomes more acute and throbbing; he becomes deaf, has all the symptoms of high fever, including, perhaps, delirium; then a discharge begins to flow from the external ear, and the acute symptoms subside.

When these symptoms first set in, leeches should be applied behind the ear, and fomentations. The patient should be purged, and those remedies, such as mercury or antimony, which appear to have the power of subduing inflammation, should be given. When the fever subsides, the discharge must be washed out with warm water and white soap twice a day, a weak tepid astringent injection poured in, and then allowed to run out again.

Earache is the term generally applied to the pain which accompanies the diseases just described; but by medical men it is used to express neuralgia of the ear. It may be known from the former varieties by its suddenly coming on, and its always being of the same degree of severity; while the pain of *otitis*, or inflammation of the ear, increases in intensity, and is throbbing. The remedies for this affection are, removing causes of nervous irritation, such as decayed teeth, and giving tonics, especially quinine and iron.

As it is absolutely necessary that the membrane of a drum, to produce sounds, should have air on both sides, the Eustachian tubes are for the purpose of allowing air to pass up from the throat to the inner surface of the membrana tympani; so it is evident that when inflammatory swelling of their lining membrane renders them impervious to air, the tympanic cavity ceases to be a drum; hence deafness from cold, or what is called 'relaxed sore throat.'

THE NOSE.

When foreign bodies are put into the nose, attempts should be made to draw them forward, either with a bent probe or a forceps, opening the latter very wide, and closing it very gently. If these attempts at removal fail, it may be pushed back into the throat. Bleeding from the nose has been treated of under the head of Hemorrhage.

Nasal polypi are generally small pear-shaped gelatinous bodies, which produce a feeling of stuffing and cold, and prevent the patient from breathing through his nostrils. They must be gently pulled away by a forceps. There are other and more serious tumours which occasionally affect the nostrils.

Fetid discharge from the nostrils or ozæna is sometimes the result of catarrh in delicate subjects. The patient has all the symptoms of a cold in the head. Inhalation of the steam of hot water, into which twenty or thirty drops of creosote have been dropped, is the most efficient remedy, combined with tonics. In scrofulous subjects, there is sometimes ulceration of the nasal mucous membrane; and this, as well as disease of the nasal bones, may be the cause of a most offensive discharge, which must be washed out with a solution of chloride of lime in warm water, injected into the nostrils by means of a large syringe.

MOUTH, TEETH, AND GUMS.

Tongue-tie is when the frænum linguæ, or bridle of the tongue, ties that organ downwards to the lower jaw. This may prevent an infant from sucking. It may be lacerated with the finger-nail, or snipped with scissors. This is an operation frequently performed, and very rarely required.

The gums of infants are sometimes inflamed over a tooth which is about to come through; a lancet should then be carried along the gum, which, by allowing a flow of blood, and dividing the swollen tissues, relieves the tension, and consequent suffering.

If a tooth be dislocated, or driven quite out of the socket, and it happens to be a healthy one, it ought to be replaced, and tied to its neighbours by a silk thread.

In some persons, the enamel covering a tooth is imperfect, allowing the fluids in the mouth to exert a chemical influence upon it; the tooth so affected then becomes what is technically termed *carious*, and crumbles down, at last exposing the central cavity and its contained nervous pulp, which being affected by constitutional or other changes, produces *toothache*.

The treatment of carious teeth is either to protect the pulp with some artificial covering—as gutta-percha dissolved in chloroform—or the patient should consult a dentist, who will, if possible, put in some more permanent stuffing.

Toothache may be relieved by scarification of the gum near the affected tooth, and a small piece of cotton-wool dipped in mastic and tannin, a drachm of each dissolved in an ounce of water; to this a little powdered morphia may be added; or the central cavity may be touched with caustic of some kind. The victims of toothache inflict much unnecessary torture upon themselves by the application of toothache tinctures, creosote, &c. The saliva contains earthy matter in solution, which is sometimes deposited on the teeth, and is called *tartar*. It produces considerable irritation, if allowed to accumulate. To prevent this happening, care should be taken to clean the teeth well every morning and night with a tooth-brush and camphor-powder. Softening and tenderness of the gums greatly annoy some persons, who are generally suffering at the same time from disordered stomach or liver. The gums are very painful, bleed readily, and the teeth drop out. The constitutional symptoms should be attended to by purges and alteratives, the mouth daily washed out with astringent gargles; and if there is much soreness, some anodyne solution may be applied.

Gum-boil begins in the socket, or near a decayed tooth; and after giving severe pain, bursts externally. As soon as it comes near enough to the surface, it must be opened, and the tooth must be pulled.

EMERGENCIES.

Drowning, or suspended animation from immersion in water, is caused by the imperfect aëration of the blood in the lungs, not from the lungs filling with water; for so perfect is the mechanism about the upper part of the windpipe, that but a small quantity of water can find its way into the air-passages. The patient dies in the same state as one who has been hanged or exposed to the inhalation of carbonic acid gas; therefore, it is evident that the old plan of turning drowned persons upside down, or rolling them in a barrel, must be not only useless, but injurious. The period of submersion necessary to destroy life has not been exactly ascertained; but three minutes and a half are quite sufficient. However, the rule is, *always to make attempts at resuscitation*, and to persevere as long as the *least* hope remains of being successful.

When the drowned man is removed from the water, he is to all appearance dead, his face livid, lips blue, jaws firmly closed, a viscid froth issuing from the nostrils, and his body is swollen. If a house be within reach, he should be taken there at once, carried carefully with the head higher than the shoulders, and a messenger should be sent on to prepare a bed, warm bath, &c. But if the accident take place at a distance from such conveniences, he should at once be stripped and dried with the clothes of the bystanders, if nothing else is at hand; and then the 'ready method,' as it is named by its inventor, Dr Marshall Hall, should be tried thus:

Lay the patient's left arm across his chest; hold his mouth open, and pull the tongue forward. Then let one

at his shoulders and another at his legs turn him over towards his left side; when *almost* over on his face, roll him back again; and so on from right to left. Dr Hall has shewn that by this movement of the body the natural respiratory efforts are more efficiently imitated than by inflating the lungs with the bellows, the mouth, or by forcibly compressing the walls of the chest; and since the publication of Dr Marshall Hall's experiments on the subject, many apparently hopeless cases have been successfully treated.

When the drowned person is brought to a house, all unnecessary attendants should be requested to withdraw. He should be then placed in a warm bath; and artificial respiration, by compressing the walls of the chest, and then allowing them to expand, should be tried repeatedly and vigorously. The sheets should be stripped off a bed, and he should be laid between the blankets, with hot bottles or bricks to the soles of the feet and armpits; the whole surface of the body should be rubbed with flannel, especially over the region of the heart. The mucus should be wiped from the nose and lips; and any one present may put his mouth to that of the drowned man, press the windpipe—Adam's apple—back against the gullet with one hand, and blow into the mouth; if the windpipe be not pressed back, the air will go into the stomach instead of the lungs.

All these efforts must be continued. Galvanism, if possible, should be tried, and the rubbing persevered in for hours. Dr Douglas has published a case in which the patient was submerged fourteen minutes, and shewed no signs of vitality till the efforts at revival had been continued for eight hours and a half. If these efforts are successful, there will be seen a short convulsive effort to breathe, repeated in a few minutes; then the heart begins to beat feebly, and respiration and circulation are gradually restored. A very little warm stimulant should now be given, care being taken that it does not pass into the windpipe.

The patient should now be carefully watched: he may at once come to himself, or may remain semi-delirious, and imagine himself still in the water. If there is much sleepiness or tendency to relapse into insensibility, he ought to be cupped at the back of the neck, to relieve the congested state of the brain.

Suffocation from Foul Air.

Carbonic acid gas, if undiluted with common air, produces spasm of the glottis or upper part of the windpipe, which closes to prevent the poison entering the lungs. It is generally found in brewers' vats and cellars. A person entering a vat sometimes drops suddenly to the ground from the effect of this gas, and, unless rapidly removed into a purer atmosphere, will undoubtedly die. He must be dragged out with grappling-irons, or some one with strength and courage may rush in and drag him out.

Remedies.—Strip the body; dash cold water on the face and chest; rub hartshorn and oil over the chest; use artificial respiration. If the surface of the body be cold, apply hot bottles, &c., to the feet; try to induce vomiting by tickling the throat. If within reach of an infirmary, take him there, and further attempts may be made with electricity and the inhalation of oxygen gas.

The air of a room may be rendered poisonous by burning charcoal in it; the slower the charcoal burns, the more carbonic acid gas is evolved, till at last any person who may be in the room becomes motionless, speechless, and insensible, dying at last in a state of stupor. Burning common coals also may generate sufficient carbonic acid gas to destroy life, if there is no chimney to the room.

Sulphuretted hydrogen is generated in drains, sewers, cesspools, &c. If breathed by itself, it at once produces unconsciousness and death. If mixed with common air, it produces vomiting and headache.

Treatment.—Removal into fresh air; artificial respiration; then stimulants, as brandy and water.

Strangulation.

The person strangled is in the same condition as the drowned man. Death, except when it has been inflicted by the professional hangmen, who generally break the neck, has resulted from the inability to receive *fresh air* into the lungs. The countenance is swollen and purple, the eyes staring open, the mouth frothy and open, and the tongue protruding, the hands clenched, and the tips of the fingers blue.

Strip the body, dash cold water on the face and chest; use the methods of artificial respiration as in drowning, and bleed from the arm or external jugular vein.

Choking.

Occasionally persons are choked by foreign bodies getting into the upper part of the throat, and so blocking up the aperture of the windpipe. It is astonishing what masses of food a hungry man will attempt to swallow, which, in their passage down the gullet, sometimes produce pain, which lasts some minutes, and is soonest remedied by large draughts of water. Sometimes a fish or rabbit bone scratches the lining membrane of the gullet, and leaves a distressing sensation of something sticking in the passage, the patient occasionally becoming very nervous and anxious, making violent attempts to get rid of it by swallowing bits of bread, drinking water, &c. If a surgeon be at hand, he should pass a whalebone *probang*, with a bit of soft sponge at its end, down the throat. In performing this operation, care must be taken not to pass it into the windpipe. Before using more severe methods, the finger ought to be passed as far as it will reach, to search for the foreign body, and hook it out.

When immediate suffocation is threatened, an opening should be made into the windpipe, which consists of an upper part or box, called the *larynx;* a middle long portion, formed of imperfect rings, the *trachea;* and the subdivisions of the latter after it has passed into the chest, one on each side, the *bronchi.* For foreign bodies in the upper part of the larynx, it is sufficient to make an opening into it just below the obstruction. This is called laryngotomy, and may be performed by any one with any cutting instrument. The urgency of the case does not allow time for surgical assistance to arrive; and many a man has died from want of the following simple proceeding:

Laryngotomy.—Pull the head back; run your finger from under the chin down the middle line of the neck. You will first feel the hyoid bone, then a depression, then the hard prominence of the thyroid cartilage, or Adam's apple; then the finger will sink into the space between the thyroid and circoid cartilages, which is occupied by a tense membrane, into which plunge a penknife, and insert a bit of the quill of a pen. If the bleeding is considerable, enlarge the skin-wound, and take up and tie the artery, which is a small one running across the membrane. Then send for a surgeon, who will conduct the after-treatment.

Tracheotomy is a more severe operation, which is simple to the anatomist, but would be full of hazard to the patient if attempted by the hands of an amateur.

THE SKIN.

When a papilla of the skin increases in size, and is covered by an unusual quantity of the scarf-skin, or cuticle, which is also sometimes hardened, the little tumour thus formed is called a *wart.* When these enlarged papillæ occur in some part of the body where they are kept constantly moistened by perspiration, their covering of scarf-skin is very thin, they are apt to bleed, and sometimes have a thin yellowish discharge.

Warts on the fingers may be snipped off, or tied with a thread round the base, or touched with caustic; they

often disappear without any surgical interference. The others should be frequently washed, and some astringent lotion applied, or be snipped off by a surgeon. Sometimes in old persons a warty growth appears on the face, which, though simple originally, may become cancerous; and the person should at once consult a surgeon.

Corns are produced by some local irritation causing an unusual growth of thick scarf-skin, and are generally found over projecting portions of bone on the toes or soles of the feet, or any part where the skin undergoes pressure.

Wash the feet in warm water. Put some soothing plaster over the corn, or a piece of thick leather with a hole punched to correspond to the corn, and so relieve the pressure. Pare the latter frequently, and wear easy shoes.

Soft corns are small irritable growths from the true skin found between the toes, and should be touched with *nitrate of silver*. When a hard corn is much irritated, the skin at its base inflames, and some matter is formed, which produces intense suffering. The corn ought to be pared down to the matter, which will give instant relief.

Boils are little hard painful swellings in the true skin, which come sometimes from too good living, at others, from too low a state of health, and at some seasons are epidemic. They should be poulticed at first, when a little slough will come away in a few days; it is better, however, to have them lanced after suppuration has once set in. Alterative medicines should be given; and to prevent their recurrence, some alkali, as a teaspoonful liquor potassæ twice a day, or soda in milk, should be taken.

ANÆSTHESIA.

Within the last few years, a great change has taken place in operative surgery, and in the treatment of all diseases accompanied by acute pain, from the introduction into general use of anæsthetics, or substances which have the power of inducing insensibility to painful impressions without injuring the constitution.

The idea of painless operations is an old one. The writers of the Augustan age mention that before the hot-iron cautery was applied, the patients were given wine, with the root of the mandragora soaked in it; and that while under the influence of this mixture, they might be cut or burned without pain. In the thirteenth century, narcotic vapours were employed to induce insensibility to surgical operations; but these humane remedies fell into disuse. In 1784, a Mr Moore in London tried the effect of pressure on the principal nerves of a limb, and in one or two instances operations were performed on limbs so treated with but little suffering; however, the pressure on the nerves was in itself so intensely painful, that it was soon given up.

After the discovery of nitrous oxide, many experiments were made; and Sir Humphry Davy suggested that it might be found serviceable in making patients insensible to the surgeon's knife. Mr Horace Wells, a dentist in America, acted upon this hint in 1844, and when under the influence of the nitrous oxide, had one of his own teeth pulled. He subsequently administered it to some of his patients, and extracted their teeth without their being conscious of the slightest pain. Wells then went to Boston to exhibit before the medical faculty; and his experiments having unfortunately failed, he was laughed out of his profession, and committed suicide in January 1844.

His pupil, Morton, who had assisted in the experiments with nitrous oxide, settled in Boston as a dentist; and in connection with Dr Jackson, endeavoured to find some means of extracting teeth without pain. They seem to have been led to try sulphuric ether, by remarking that its vapour was used as a remedy for spasmodic affections of the chest. Morton inhaled it himself on the 30th of September 1846, from a tube communicating with a flask containing the ether; and thus he is undoubtedly the discoverer of a manageable method of administering its vapour. No sooner was he awake after this first inhalation than he longed to try it on some one else, and offered five dollars to any one who would allow him to pull a tooth.

While he was anxiously waiting for a patient, Eben Frost, a nervous, frightened man, came into his surgery wanting a tooth pulled, but begged to be mesmerised, as he dreaded the pain. He was persuaded to inhale ether, became unconscious, and remained so while Mr Morton extracted a large double tooth. This case, which occurred at 19 Tremont's Row, Boston, on the 30th of September 1846, is the first in the modern era of anæsthesia in surgery.

The news having arrived in England, that great surgeon, the late Mr Liston, on the 21st of December 1846, administered ether to a patient in University College Hospital, in London, and removed the toe-nail, a most painful operation. Mr Liston's example was soon followed by Mr Fergusson, in the King's College Hospital; and surgeons in all parts of the kingdom soon made trials of it.

But the reign of sulphuric ether as an anæsthetic was doomed to be a short one; for, on the 4th of November 1847, Professor Simpson of Edinburgh discovered the anæsthetic powers of chloroform.

This is a heavy colourless fluid, which was discovered by Soubeiran in 1831. It is obtained by distilling rectified spirit with water and chloride of lime, has a specific gravity of 1·497, and boils at 140°. It has a pleasant fruity smell, and is now so well known, that further description is unnecessary.

The best way to administer chloroform is from a handkerchief; and attention should not so much be paid to the quantity administered, as to the symptoms produced. When insensibility is complete, the eyeball may be touched without winking, and the muscles are relaxed. This state should be kept up by occasional inhalations, but care must be taken not to let it be more profound, lest the patient get into a state of coma, and his life be in danger. No food should be taken for a few hours before inhaling chloroform. Non-professional persons should not, as a general rule, give chloroform to themselves or others, as, like every other remedy, it may do harm when unskilfully administered. Some persons are hysterical under its influence, but that soon passes off, and there is seldom any unpleasant sensation experienced upon waking, but generally one of wonder and thankfulness. Operations can now be performed under its influence in almost all cases where operations are themselves justifiable. Delicate patients are spared the shock and alarm of the operation; and children, instead of being, as formerly, mad with terror, now lie in a quiet sleep; and not only is the patient benefited by being spared suffering, but the operator can perform the various steps of the operation more leisurely and satisfactorily than he could during the struggles and cries of his subject, however great his nerve or experience in the use of the knife might have been.

In some few cases, intense cold may be applied to the surface of the skin through which the knife is to pass. Dr Arnott uses a mixture of pounded ice and salt.

Mesmerism has not found many advocates among medical men, for though it is certain that occasionally a person is met with who is susceptible to the influence of the mesmeric passes, still the majority of Europeans are happily too sound in mind and body to allow of mesmerism being of general use for the relief of pain; and it is scarcely desirable that persons should be brought into a state of hysterical catalepsy when they can safely and speedily be thrown into a profound sleep by the inhalation of chloroform.

CLOTHING—COSTUME.

WHETHER inhabiting a tropical, temperate, or arctic region—existing in abject barbarism, or enjoying the highest degree of civilisation and refinement, man is essentially a clothing animal. *Some* kind of covering or decorative appendage he always affects, being instigated to this necessity by motives of defence, shelter, decorum, or vanity. From the simple head-dress and loin-cloth of the South-sea islander, to the elaborate costume of the gay Parisian, the ruling principle is much the same; more rational, perhaps, in the case of the savage than in that of the individual laying claim to superior enlightenment. In obeying this clothing instinct or necessity, attention is always paid, not only to the kind and quality of the covering, but to the form and manner in which any particular article of dress shall be worn. Thus originates the distinction between clothing and costume—the one having reference to the fitness of the material for the purposes of shelter or protection, the other having reference to taste or a sense of the becoming, though often marred by the absurdities of vanity and caprice.

CLOTHING.

Admitting the above distinction, and laying aside consideration of all dress or armour of a defensive kind, clothing must be regarded simply in the light of a protection from the extremes of heat and cold, so that the body may perform its functions healthfully and without obstruction. Keeping this purpose in view, and also bearing in mind the nature and action of the human skin (see No. 8), 'it is easy to deduce that clothing should be of such a nature as not to impede the necessary escape of perspirable matter, but to suffer it to pass through its texture; that it should be of such a non-conducting quality as to confine the heat generated by the blood sufficiently to preserve the activity of the nervous system; and that, by its lightness, softness, and pliancy, it should permit the free motion of the limbs.' Clothing which would subserve all these purposes, would be nearly perfect in its hygienic properties; and such an attire we could readily assume, were it not that considerations of economy, special avocations, and the like, are always interfering less or more to disturb the equilibrium. With these preliminary remarks, and referring the reader for further information on the general hygiène of dress to the article PRESERVATION OF HEALTH, we shall now consider the peculiar characteristics of British clothing.

Quality of Clothing.

Woollen fabrics, as articles of clothing, have several advantages over other materials. They are bad conductors of heat; hence their warmth by preventing the heat of the body from escaping, and their utility in preserving the equability of its temperature, though exposed to sudden changes. From their filamentous texture and elasticity, they are light and pliable; and yet, from their peculiar property of being *felted*, they can be prepared to any degree of weight and thickness. They possess also the property of not being easily wetted, while they are sufficiently porous either to absorb or to permit the escape of all cutaneous exhalations. Further, when worn next the skin, their rough and uneven surface produces in every motion of the body a gentle friction, which greatly assists and promotes the functions of the minute cutaneous vessels and nerves. 'In a climate like ours, which is so variable, and usually so cold, the article of dress that is worn next the skin ought always,' says Dr Robertson of Buxton, 'to be a bad conductor of heat at all events. In general, flannel of an adjusted degree of thickness and fineness answers this intention sufficiently well, without proving to be too heating, or irritating, or relaxing. In summer-time, if the flannel which proved to be well borne in the colder seasons of the year, should be so far irritating and heating as to relax or fever the system, this may be remedied by substituting for it a thinner and finer quality of flannel; or in extreme cases of this kind, an under-garment of calico, of a proper degree of thickness, may be substituted for the flannel at that season of the year.' The use of chamois leather as the under-garment is objectionable.

But, strongly as the importance of having a bad conductor of heat next the skin should be impressed on the mind, there is a point connected with it which is almost as important. The inner garment, especially if made of flannel, ought not to be worn during night. It ought invariably to be taken off at night, and as invariably

resumed in the morning. In bed, it is unnecessary: it is worse than unnecessary, for it does harm: it then stimulates the skin, and produces a preternatural waste of the secretions, and corresponding debility of system —a corresponding liability to suffer from the depressing influence of cold—a corresponding incapability of resisting its influence. But, further, removing this garment during the night relieves it from the scurf, some degree of dampness, and other impurities which it must acquire during a day's wear, and so renders it fresh and more agreeable to the sensations of the wearer. Not wearing it at night renders it more effectual in protecting the surface from the cold by day, on the principle that a great-coat is not of the same service to the wearer when out of doors, if he is in the habit of wearing it in the house. It would be easy to adduce strong evidence in behalf of the value and importance of wearing flannel next the skin. 'Sir John Pringle,' says Dr Hodgkin, 'who accompanied our army into the north at the time of the Rebellion, relates that the health of the soldiers was greatly promoted by their wearing flannel waistcoats, with which they had been supplied on their march by some Society of Friends;' and Sir George Ballingall, in his lectures on military surgery, adduces the testimony of Sir James Macgrigor to the statement that in the Peninsula the best-clothed regiments were generally the most healthy; adding that, when in India, he witnessed a remarkable proof of the usefulness of flannel in checking the progress of the most aggravated form of dysentery in the second battalion of the Royals. Captain Murray told Dr Combe that 'he was so strongly impressed, from former experience, with a sense of the efficacy of the protection afforded by the constant use of flannel next the skin, that when, on his arrival in England, in December 1823, after two years' service amid the icebergs on the coast of Labrador, the ship was ordered to sail immediately for the West Indies, he ordered the purser to draw two extra flannel shirts and pairs of drawers for each man, and instituted a regular daily inspection to see that they were worn. These precautions were followed by the happiest results. He proceeded to his station with a crew of 150 men; visited almost every island in the West Indies, and many of the ports of the Gulf of Mexico; and, notwithstanding the sudden transition from extreme climates, returned to England without the loss of a single man, or having any sick on board on his arrival. It would be going too far to ascribe this excellent state of health solely to the use of flannel; but there can be little doubt that the latter was an important element in Captain Murray's success.'

There can be no doubt that flannel is by much the best article for being worn next the skin when the body has to be exposed to such a temperature, or to such a severe degree of exercise, as increases the perspiration in a material degree. The common practice among the workmen in potteries, foundries, collieries, &c., of wearing thick flannel shirts, tends much to preserve their health, under the circumstance of the profuse perspiration caused by the excessive labour they are called upon to undergo, or the extreme heat of their places of work, alternated as this must be with the much colder atmosphere out of doors, amounting, it may be, to a difference of temperature of no less than 60° or 70°. Dr Kilgour, in his *Lectures on Therapeutics and Hygiène*, says 'that the use of flannel was found to be beneficial in the prevention of cholera, by maintaining the equilibrium of the temperature and the functions of the skin, and thereby preventing that derangement of the bowels which is so general a consequence of cold applied to the surface.' To the preceding excellent testimony, we may add that woollen fabrics, from their ready elasticity, are less liable than any other species of clothing to interfere with the circulation of the vital fluids, or prevent the free and easy motion of the body.

Cotton, though greatly inferior, ranks next to wool in non-conducting properties. From its comparative cheapness, lightness, and the facility with which it can be cleaned, it has of late years been gradually superseding the use of flannel as an underclothing. But, though recommending itself for these reasons, it can by no means be considered as a perfect substitute for flannel, whether used in a pure state or when mixed with a certain proportion of wool. Its ultimate fibre is altogether different; being void of that springy softness and elasticity so peculiar to wool, and incapable, moreover, of being felted to any thickness without becoming hard, heavy, and obstructive. Further, it is far from being so absorbent, is more readily wetted, and requires therefore to be more frequently changed and submitted to the laundress. Nevertheless, it is a valuable staple of dress, and is in general use both as under and exterior clothing from the tropics, of which it is a native produce, to the limits of the polar circle.

We have said that cotton is inferior in its non-conducting properties to wool—that is, all things being equal, cotton fabrics form a cooler dress than those of woollen. These remarks apply to our own climate; let us hear the opinion of the authority already quoted in reference to the requirements of tropical regions:— 'Cotton, from its slowness as a conductor of heat, is admirably adapted for the tropics. It must be recollected that the temperature of the atmosphere, in the open air, in the hot season, exceeds that of the blood by many degrees; and even in the shade it too often equals, or rises above, the heat of the body's surface. Here, then, we have a covering which is *cooler* than linen; inasmuch as it conducts more slowly the *excess* of external heat *to* our bodies. But this is not the only advantage, though a great one. When a *vicissitude* takes place, and the atmospherical temperature sinks suddenly far below that of the body, the cotton, still faithful to its trust, abstracts more slowly the heat *from* our bodies, and thus preserves a more steady equilibrium there. To all these must be added the comparative facility with which it absorbs the perspiration; while linen would feel quite wet, and, during the exposure to a breeze under such circumstances, would often occasion a shiver, and be followed by dangerous consequences. That woollen and cotton should be *warmer* than linen in low temperatures will be readily granted; but that they should be *cooler* in high temperatures will probably be much doubted. If the following easy experiment be tried, the result will decide the point in question:—Let two beds be placed in the same room at Madras, we shall say when the thermometer stands at 90°, and let one be covered with a pair of blankets, the other with a pair of linen sheets, during the day. On removing both covers in the evening, the bed on which were placed the blankets will be found *cool* and pleasant, the other, uncomfortably warm. The reason is obvious. The linen readily transmitted the heat of the atmosphere to all parts of the subjacent bed; the woollen, on the contrary, as a non-conductor, prevented the bed from acquiring the atmospherical range of temperature, simply by obstructing the transmission of heat from without. This experiment not only proves the position, but furnishes us with a grateful and salutary luxury, free of trouble or expense.

'From this view of the subject, *flannel* might be supposed superior to *cotton;* and indeed at certain seasons, in particular places—for instance, Ceylon, Bombay, and Canton—where the mercury often takes a wider range in a very short space of time, the *former* is a safer covering than the latter, and is adopted by many experienced and seasoned Europeans. But in general the use of flannel in the tropics is inconvenient for three reasons:—1. It is too heavy—an insuperable objection; 2. When the temperature of the atmosphere ranges pretty steadily a little below that of the skin, the flannel is much too *slow* a conductor of heat *from*

the body; 3. The spiculæ of flannel prove too irritating, and *increase* the action of the perspiratory vessels on the surface, when our great object is to *moderate* that process. From the second and third objections, indeed, even cotton or calico is not quite free, unless of a fine fabric, when its good qualities far counterbalance any inconvenience in the above respects. In some of the upper provinces of Bengal, when the summer is intensely hot and the winter sharp, the dress of the native shepherds, who are exposed to all weathers, consists in a blanket, gathered in at one end, which goes over the head, the rest hanging down on all sides like a cloak. This answers the triple purpose of a *chattah* in summer to *keep out* the heat, of a tent in the rainy season to throw off the wet, and of a coat in the winter to defend the body from the piercing cold.' To this may be added, that no tropical head-dress can compete, in point of comfort and safety, with the loose, light-coloured turban of calico.

Linen, though inferior both to cotton and wool as a non-conductor of heat, and absorbent of moisture, is now extensively used as an article of inner clothing. In this capacity it has been of essential service to personal cleanliness, rendering the bath less necessary in modern Europe than in any other region of the globe. It is comparatively cheap, is easily kept clean, and its snowy whiteness enables us at once to detect when it is soiled or unfit for wear. It has been said by some one in jest, that 'a change of linen is a luxury;' and really so it is when well washed, bleached, and dried under the open air. There is a freshness and positive feeling of comfort about it not to be found in any other fabric however costly or fine. On the other hand, it must be confessed that linen has many disadvantages as an article of inner clothing. Being denser in the fibre than cotton, and much more so than wool, it forms a good conductor of heat, and thus rapidly robs the skin of its free caloric; hence the cold feeling experienced when linen is just put on. But though rapidly conducting the heat, it has little capacity for moisture, and thus soon becomes saturated, leaving the pores of the skin clogged and obstructed, unless the garment be frequently changed. Having little elasticity of fibre, it forms a smooth and dense fabric, totally void of that stimulating function often so much valued in flannel. From the experiments of Count Rumford, it appears that linen does not attract dampness so readily as wool, hair, or other animal substances; nevertheless, when it is damp, it is more prejudicial than these, and therefore requires to be well dried and aired before being worn.

Silk, as a non-conductor of heat, ranks next to cotton; but its qualities in this respect depend in a great measure upon the kind of fabric into which it is woven. Generally speaking, silken fabrics are light and thin; articles of luxury and ornament rather than of everyday utility. Nevertheless, silk possesses several valuable hygienic properties, of which the most curious and least understood is that appertaining to its electric qualities. It is found (see No. 17), that on the whole the state of the body when healthy and vigorous is *positive*, or that a surplus of positive electricity tends always to appear on the surface, from the actions of the vital organs; but that, after severe labour, hard exercise, and exhaustion, the state of the free electricity generally changes to *negative*. It is not improbable that when the actions of electricity on the animal system are better understood, it may be possible to use artificial methods of maintaining, under all circumstances, the charge that is identical with health and activity: we have acquired, by means of our houses, clothing, and fires, an almost perfect command of the element of heat; and it is to be hoped that we may some day attain an equal command over the element of electricity, and keep at a distance the deleterious negative charge as effectually as we defy the winter cold. On this important subject, so far as the influence of silk—which is an excellent non-conductor of electricity—is concerned, Drs Robertson and Carpenter have the following interesting remarks, which we transcribe at length:

'However little or unsatisfactory our knowledge of the operations of this remarkable agent in the animal economy, there is no doubt that electricity fulfils important and necessary purposes in the living system, and that a certain amount of positive or negative electricity is being constantly given off from the surface of the body in greater or less degree, according to sex, temperament, weather, the nature of the clothing, &c. It has been said that the skin and most of the internal membranes are in opposite electrical conditions; and, according to a theory of Dr Wollaston, the existence of free acid in the urine and gastric juice marks the prevalence of positive electricity in the kidneys and the stomach; whereas the existence of free alkali in the bile and the saliva indicates an excess of negative electricity in the liver and the salivary glands. Whether this view be tenable or not, it seems that the living body is never in a state of perfect electrical equilibrium with the substances or bodies around it, unless it be maintained by free contact with them; and it is stated, in illustration of this, that if two persons, both insulated, join hands, sufficient electricity is developed to influence the electrometer. Some electric disturbance is manifested by almost every individual, if it be carefully sought for. In men, it is most frequently positive; and irritable men, of sanguine temperament, have more free electricity than those of phlegmatic character; whilst the electricity of women is more frequently negative than that of men. Some individuals exhibit these phenomena much more frequently and powerfully than others. There are persons, for instance, who scarcely ever pull off articles of dress which have been worn next the skin without sparks and a crackling noise being produced, especially in dry weather; this may, however, be partly due to the friction of these materials on the surface, and with each other, as it has been proved to be greatly influenced by their nature. The most remarkable case of the generation of electricity in the human subject at present on record, is one that has been met with in America (*American Journal of Medical Science*, January 1838). The subject of it, a lady, was for many months in an electric state so different from that of the surrounding bodies, that whenever she was but slightly insulated by a carpet, or other feebly conducting medium, sparks passed between her person and any object which she approached. From the pain which accompanied the passage of the sparks, her condition was a source of much discomfort to her; when most favourably circumstanced, four sparks per minute would pass from her finger to the brass ball of the stove, at the distance of one and a half inch. The circumstances which appeared most favourable to the generation of electricity, were an atmosphere of about 80°, tranquillity of mind, and social enjoyment; while a low temperature and depressing emotions diminished it in a corresponding degree. The phenomenon was first noticed during the occurrence of an aurora borealis; and though its first appearance was sudden, its departure was gradual. Various experiments were made, with the view of ascertaining if the electricity was generated by the friction of the articles of dress; but no change in these seemed to modify its intensity. It was no doubt generated, or the electrical equilibrium was disturbed in an undue and very extraordinary degree, by the condition of the nervous system, probably influenced by some deranged condition of certain of the organic functions. It seems to have been proved that electrical manifestations are the invariable consequence of the action of the nerves in producing muscular action; and it is probable that this powerful agency of electricity exercises an important influence on the digestive processes, and perhaps especially in facilitating the decomposition of the food, and so far preparing it to enter into new combinations for the nutrition of the body. But however this may be, and however large, or little important, the influence of electricity may be in

carrying on the vital and organic processes of the system, there is no doubt that a certain amount of electrical matter is constantly being given off from the surface of the living body; that the amount of this varies according to the dryness or dampness, the coldness or warmth, of the atmosphere; and that the degree to which it is permitted to escape may be influenced by the nature of the clothes, and particularly according to the nature of the fabric which is worn next the skin; and that the escape of this electricity is so far attended with diminished power and energy of the general economy, and in the same degree to which such escape may be prevented, is the system maintained in a state of more vigorous vitality. The depressing influence of wet and cold weather may be largely referrèd to the effect of such an atmosphere in carrying off rapidly the free electricity of the system; and the colder and more damp the climate man lives in, the more important is it that he surround the body with such articles of clothing as will check, as far as may be, the escape of this extraordinary agent; and the greater the habitual depression and debility of the economy, the less the degree of its vital energy, the more important does this consideration become.

'Silk, as a remarkable non-conductor of electricity, deserves to be made use of more generally than it is in this country, as an article of underclothing. For this purpose, it should be woven entirely of what is called *bright* or *wrought* silk, in contradistinction to what is called *spun* or *spurious* silk; and the under-garment is to be manufactured in a similar way, and of a similar material, to stockings; but woven with much thicker thread into a very thick and heavy fabric.'

Furs and *down* are by far the warmest materials, but in Britain they can scarcely be considered as articles of general clothing. Soft, light, elastic, they constitute excellent adjuncts during the winter months, while their fine colours and markings add greatly to their appearance. When worn, as furs usually are, with the skin attached, they are rather impermeable to exhalations, and are not in this light to be considered as equal to the finer fabrics woven or knitted from wool. *Leather*, unless peculiarly prepared (as chamois), is by no means fit to be worn as an inner garment; in fact, the common application of this material is for boots and shoes, for which it is admirably suited by its strength and durability. Unless made somewhat easy, so as to allow room for a worsted sock or stocking and a certain amount of air, leathern boots form but a cold covering, at the same time that they are all but impermeable to any kind of exhalation. When well manufactured, leather should be soft and pliable; and when fashioned into shoes, these should be rather large and easy. There is, in general, no member of the body more sinned against—the chests of stay-wearing ladies scarcely excepted—than the foot; and the certain penalty is corns, callosities, and deformities, an unspeakable amount of pain, and in the long-run, a partial destruction of the powers and functions of one of the most essential of the bodily organs. The feet, with proper treatment, ought to be as free from disease and pain as the hands, their structure and adaptation to the wants and comforts of man being naturally perfect. 'Thirty-six bones and thirty-six joints,' says a writer on the foot, 'have been given by the Creator to form one of these members, and yet man cramps, cabins, and confines this beautiful arrangement of 144 bones and joints—together with muscles, elastic cartilage, lubricating oily fluid, veins, and arteries—into a pair of boots or shoes, which, instead of forming a protection, produces the most painful and permanent injuries.' These objections as to room cannot be urged with the same force against the numerous *elastic fabrics* now coming into use, as these, to a certain degree, expand and contract according to the requirements of the foot; but then there is this objection—all of them are impermeable to perspiration. The foot while heated perspires, the moisture is not allowed to exhale, and on resuming a state of rest, cold and damp is the result. This objection, indeed, is fatal to all the elastic *waterproof fabrics* now so much in vogue: the insensible perspiration must be absorbed or exhaled, and if not, discomfort and disease are the inevitable consequences. Numerous ingenious attempts have been made to remedy these defects, so as to retain the other valuable properties of elastic and waterproof clothing; but as yet we have seen none completely successful; and for our own parts, we would rather undergo a drenching which can be laid aside with the garment which sustains it, than sit for hours enveloped in offensive exhalations.

Amount of Clothing.

The amount of clothing should be regulated as much as possible in reference to the climate under which we live, the season of the year, the degree of exposure to which we are subjected, the exercise or fatigue we undergo, the food consumed, age, sex, and other constitutional peculiarities. Thus, other things being equal, a cold climate requires a heavier and thicker dress than a warm one: in winter we could not wear a light summer dress with impunity; a man undergoing healthful exercise in the open air needs less muffling up than a sedentary dweller within doors; the individual enjoying a full invigorating diet feels comfortable in garments under which an ill-fed man would shiver; and, generally speaking, the young and vigorous require less clothing than the aged and infirm. Regarding the first of these circumstances as axiomatic, let us consider the others in detail.

1. Although it is proper to adapt the warmth of our clothing to the season of the year, yet change in this respect must be made with caution. The animal constitution is no doubt endowed with considerable plasticity; but that plasticity must be operated upon by insensible gradations. 'Very light clothing during the summer months,' says an able writer on domestic economy, 'exposes the body to the effects of those sudden changes of weather which we experience in our climate. It is safer to wear the same clothing nearly all the year than to make frequent and sudden changes; exercise under too warm a dress occasions violent perspiration, the effects of which are often dangerous. It is remarkable that in some countries custom differs materially from ours respecting clothing. We dress in general somewhat warmer when we go out than when we sit indoors: the Turks, who seldom have fires in their apartments, keep themselves comfortable within doors by using warmer clothing than when they go out, considering the practice of moving about a source of heat, which it really is: the Chinese of rank, it is said, practise the same mode—putting on an additional garment in the house, which they throw off as the sun ascends to the meridian, and resuming it in the cold of the evening.' 2. As to exercise, there can be no doubt that it is a source of heat: respiration goes on more briskly, the carbon of our food and blood is more rapidly consumed, a greater degree of heat is experienced, and this continues so long as the body is in a healthful vigorous condition. To overload one's self with dress during exercise is but to irritate and fatigue; at the same time care is required on relapsing into a state of rest, that the exhausted frame be properly protected. During exhaustion every function goes on less briskly, little heat is supplied by respiration, and that little requires to be carefully retained. 3. The same remarks are applicable to the case of food. A well-fed man (see PHYSIOLOGY) has a source of heat within him; and if the doctrines of Liebig and others be correct, food may be said to supplement clothing, and clothing food. If we lose heat through lack of clothing, the food must supply it; and *vice versâ*. 4. The young and vigorous, other things being equal, require less clothing than the old and infirm. While the respiration and circulation of the system is vigorous, and the diet wholesome and full, every function is performed with

activity; heat is freely formed; and the exercise generally taken by the young greatly augments the supply. But the young and vigorous must not neglect the ordinary rules of clothing on this account—a neglect they are but too apt to perpetrate, and which, in the case of infancy, is too often perpetrated against them by ignorant nurses, and equally ignorant and foolish mammas. 'Are the little "Highlanders,"' asks Dr Erasmus Wilson, 'whom we meet during three out of the four quarters of the year under the guardianship of their nursery-maids, dawdling about the streets in our public walks or squares, properly protected from the cold? Are the fantastically attired children whom we see "taking an airing" in carriages in our parks, sufficiently and properly clad? If these questions can be truly answered in the affirmative, then, and then only, my remarks are needless. There can enter into the parent mind no more baneful idea than that of rendering children "hardy" by exposing them unnecessarily to cold, and by clothing them inefficiently. I have known instances wherein parents, acting on this principle, have failed entirely in rearing their offspring. Does nature treat her progeny thus? Does she not, first of all, insure the birth of her young only at a kindly season, and then provide them with downy coverings, warm nests, and assiduous protectors? And WE must imitate nature, if we would give to Britain a race capable and worthy of maintaining her independence and honour. The little denizens of a warm nursery must not be subjected, without a carefully assorted covering, to the piercing and relentless east or north-east wind; they must not be permitted to imbibe the seeds of that dreadful scourge of this climate—consumption—in their walks for exercise and health; they must be tended, as the future lords of the earth, with jealous care and judicious zeal. *One-sixth of the deaths of young children*, it must be remembered, *result from cold.*' 'The large mortality,' says another medical authority, 'among the children of the poor, is to be referred to an undue exposure of their feebly acting and sensitive surfaces to the influence of the cold.' It by no means follows, however, from what has been said, that the systems of the young are to be overheated, relaxed, and enfeebled by an excessive amount of clothing, an amount disproportioned to the requirements of health and growth.

As to special articles of dress, and the clothing of special parts of the body, there is often injudicious management, partly from mistaken physiological notions, and partly from caprice and fashion. Thus there is nothing more common than to dress heavily when we go out of doors, and put on some thin flimsy covering within doors; to clothe well during one portion of the day, and be in loose, open, undress during another; to wear strong boots or shoes when we take open-air exercise, and immediately thereafter to be sedentary and in slippers. Such sudden changes are contrary to all reason, and cannot fail to be prejudicial to sound health and comfort. The human body is not a piece of mechanism, which can be wound up and adjusted at pleasure; and far less is it to be tampered with in direct opposition to the natural laws under which it is constituted. What more preposterous than to dress heavily when under the warming influence of exercise, and to dress loosely and lightly when sedentary, and when all the functions of circulation and respiration are languid and slow! Another error, very common in this country, is the inordinate wrapping of the neck and shoulders with kerchiefs, shawls, and furs. To behold men and women, old and young, all be-muffled and be-boa'd, no matter what the day or what the occasion, a stranger would be apt to imagine the country labouring under one huge epidemic; and yet the truth might be some absurdity of fashion—some monkey imitation of A by B, C, D, and all the other letters of the alphabet. 'Unless when much or unusually exposed to the influence of cold,' says a high medical authority, 'the risk of local relaxation from this practice, and of an unadvisable degree of chill when such extra clothing is removed, deserve consideration, and may lead to greater evils than such extra wrapping is calculated to obviate. It is only justifiable under circumstances of extreme and long-continued exposure to cold, or in the instance of very delicate and susceptible systems.'

Another instance in which very irrational and often fatal errors are committed, is the due protection of the feet. 'Of all parts of the body,' says the same authority, 'there is not one the clothing of which ought to be so carefully attended to as the feet. The most dependent part of the system, this is the part in which the circulation of the blood may be the most readily checked; the part most exposed to cold and wet, or to direct contact with good conducting surfaces, it is the part of the system where such a check is most likely to take place. Coldness of the feet is a very common attendant on a disordered state of the stomach; and yet disordered stomach is not more apt to produce coldness of feet, than coldness of feet is apt to produce disorder of the stomach; and this remark does not apply only to cases of indigestion, but to many other disorders to which man is liable. Yet do we see the feet of the young and delicate clad in thin-soled shoes and as thin stockings; no matter whether the weather is dry or damp, or whether the temperature of the atmosphere is warm or cold. But this is not the whole of the evil. These same feet are frequently, at different times of the day, differently covered as to stoutness of the shoes and their soles, and very often likewise as to the thickness of the stockings. . . . . I am sufficieut of a Goth to wish to see thin-soled shoes altogether disused as articles of dress; and I would have them replaced by shoes having a moderate thickness of sole, with a thin layer of cork or felt placed within the shoe, over the sole, or next to the foot. Cork is a very bad conductor of heat, and is therefore to be preferred. Its extreme lightness, the remarkable thinness to which it may be cut, its usefulness as a non-conductor not being greatly impaired thereby, and the inappreciable effect it has on the appearance of the shoe, all seem to recommend its use for this purpose in the strongest manner.'

Among the special instances of error as to the amount of clothing, the writer just quoted places pre-eminently that of bed-clothes. In Britain, where a great variety of material is used—such as feathers, down, hair, woollen blankets, cotton counterpanes, and linen sheets—this subject is deserving of more attention than it generally receives; and all the more seeing that while in bed the skin usually throws off much more of its secretions than at other times. What is required is a mere sufficiency to keep the surface warm; everything beyond this is exhausting and detrimental. What is sought for in bed is rest, quietude, and a total avoidance of all excitement; and this most certainly cannot be obtained when half-smothered, heated, and irritated by an undue amount of warm clothing. 'A free and sufficient use of exercise, and particularly walking-exercise; a regular exposure to the open air; a daily change of air, as far as may be practicable—walking as far away from home as strength, and time, and weather allow, instead of confining the exercise to a circle near the house; and a regulated diet, are the great means, next to sufficiently frequent ablutions, of keeping the vessels of the skin in a state of efficient activity, and preserving or restoring the natural temperature of the surface. And this point having been gained, very few and light bed-clothes are all that will be required.

COSTUME.

Dress may be said to consist of three generic forms—the simple attire of savage life, in which a skin, blanket, or some other loose covering, is nearly all that is employed; the flowing and elegant dress of the East;

and the precise and more closely fitting clothing of modern European nations. Of the first mentioned, little need be said. In the absence of manufactured articles, savage tribes in all countries are, and have been, in the habit of attiring themselves in such rude materials as nature has placed within their reach. The Indian of North America clothes himself in skins on which the fur is left, or with a blanket procured from the wandering trader. His legs and feet he dresses in moccasons made from a species of leather, and in full dress he fancifully paints his skin with pigments. In some of the islands of the Pacific—as also till lately in New Zealand—the inhabitants *tattoo* the surface of the body, by puncturing it with an instrument, and inserting coloured juices in the wounds. Such, likewise, was the barbarous practice and fashion of the original inhabitants of the British Islands.

North American Indian.

Throughout Asia, in North Africa, and in Turkey, the dress is generally of a loose and flowing form, that of the common people in China being least so. The *turban* is almost universal. It is a male head-dress, composed of muslin swathed in folds, for the most part round a cap; and by presenting a mass of light material to the sun, it is considered to be a suitable covering for the head in Eastern climes. The forms of this head-dress, however, differ considerably, some being more tasteful than others. The first represented in the accompanying figure is the round turban common in Africa; the second, an elegant modern Egyptian form.

A crowd in Constantinople, previous to the late modifications of costume, was, says a traveller, a picturesque group: 'there was the graceful Effendi Turk with snow-white turban, jetty beard, sparkling and full eyes, long flowing caftan, scarlet trousers, yellow boots, rich Cashmere shawl round the waist, in which shone the gilded dagger; next was the gay but cunning-looking Greek, with short chin, black turban, enormous but short trousers, bare legs, and black shoes; then the grave Armenian, with his calpac of black felt balloon-like upon his head, his long Turkish robe, silver ink-horn in his girdle, and his feet in the crimson slipper or boot; next was the Jew, with his blue turban and slippers; and with these were seen the high taper calpac of the Tatar, the melon-shaped head-piece of the Nizam Djedid, the gray felt conical cap of the imam and dervish, and occasionally the ungraceful hat of the Frank, with the be-buttoned and mean-looking costume of Western Europe.'

The dress of the modern Greeks is a mixture of Eastern and European costume, with little to mark the classical origin of the people. The chief article of attire of the poorer Greeks is a *capote*, or large woollen garment, with a hood, shaggy with short threads of yarn; it is heavy when dry, but nearly insupportable when wet; it is as serviceable for home and bed to the wandering Greek as the *bunda* is to the Hungarian shepherd, and it is a perfect defence against cold and dew. All but the poor classes of Greeks, however, dress showily, and even a servant will expend every farthing of his wages in fine clothes. Thus a physician's janizary may be seen in a rich robe of scarlet, his vest of blue velvet trimmed with gold-lace, and in his silk girdle a brace of pistols embossed with silver; turban, short petticoats, and trousers of purest white, and gaiters or 'leggings' of scarlet velvet, embroidered with gold; altogether, a costume that might suit a prince. The general dress consists of a short embroidered jacket, without collar, and with sleeves open from the elbow; an embroidered vest, a cotton shirt, a tunic of several folds, secured by a sash or shawl about the waist, and reaching to the knee; loose breeches or trousers, short socks, and slippers between sandals and shoes. In one corner of the sash, the common people carry their money, which the rich put into purses, and carry, with their handkerchiefs, watches, and snuff-boxes, in their bosoms. The head-dress is various; as the turban, *à la Turque;* the fur-cap, like a muff; the fez or tasselled cloth cap, worn on one side; the plain caps of the peasantry; and skull-caps of velvet or gold, embroidered and tasselled. The young Greeks are the handsomest race in Europe; their long hair falls over their shoulders from under the cap; their embroidered jackets, vests, and buskins, their arms mounted with silver, and even jewels, and their white kilts, compose, on the whole, one of the most graceful and becoming costumes in the world.

The Greek.

The costume of the Greek female more closely resembles that of the Turks. She wears loose trousers of fine calico, embroidered with flowers, a closely fitting vest, a jewelled zone about the waist, and a long-sleeved gown, flowing off loosely behind, or a veil covering the body; and sometimes a rich pelisse trimmed with fur. Jewellery is worn to excess; and bracelets of gems, or strings of gold coins round the arm and neck, across the forehead, and in the hair, which the younger girls let fall down their backs and over their brows and cheeks. Little caps, similar to those of the men, are also worn by the females, studded with coins, but worn on one side of the crown, the girls wearing in them flowers, and the matrons heron-plumes or jewels. The young women often dye their hair auburn, and the old ladies red, with which colour the nails are also tinged. The females walk abroad in a robe of red or blue cloth, and an ample muslin veil.

The dress of modern Europe, and, we may add, that of civilised America, differs little in essentials. With few exceptions, it is well fitted for an active, hard-working, city-dwelling people; it has little cumbrous or unnecessary about it, and if not always so graceful or picturesque as could be wished, it is free at least from the reproach of 'barbaric pomp and ornament.' Climate, business avocations, and conventional usages, require it to be somewhat precise; but this precision can never become ridiculous unless through some temporary freak of what the gay world denominates *fashion*. The usual notions concerning flowing or classical costume are more traditionary than rational; for if there be really anything in 'the human form divine,' the less that any costume clogs, and cumbers, and conceals it—consistently with comfort and decorum—the more becoming must it of necessity be. With this much for the too often reviled costume of modern Europe, and without entering into particulars

as to the styles it assumes in different countries, we shall now devote the remaining pages to the history and development of

BRITISH COSTUME.

Partly from a wider acquaintance with other countries, partly from the introduction of new pursuits and avocations, and partly from caprice and fashion, the costume of our country has undergone many changes in the course of ages. Among the Southern Britons, at the time when Julius Cæsar landed in the country (55 B.C.), the arts connected with clothing had made some advance; but in the more northern parts, the practice of living half-naked, with painted and tattooed bodies, was common, and, notwithstanding the severity of climate, remained till a much later period. Such fanciful decorations are supposed to have given name to the nation of *Picts* (from the Latin word *picti*, painted); but on better authority, the appellation has been referred to a different origin.

Pict.

The usual Roman dress, in the latter period of the Empire, consisted of a tunic, or loose upper garment, with a dress for the lower limbs, called *braccæ;* hence the modern term *breeches*. Over all was occasionally worn by the higher classes the *toga*, or mantle. It is believed that these Roman costumes were generally copied by the greater number of British, at least among the more opulent classes. In the dress of the women, however, there was but little change. They appear in two tunics, the one reaching to the ankles, the other having short sleeves, and reaching about half-way down the thigh: in other words, they resemble a round gown, or bed-gown and petticoat, though the latter, distinct from a body and sleeves, is not considered to be ancient. This tunic was called in British *gwn;* hence our word *gown*, of which we still see specimens of short dimensions worn by women of the humbler classes in England, Scotland, and Wales.

Anglo-Saxon and Danish Periods.

The Anglo-Saxon and Danish periods of English history are marked by new peculiarities in costume. Soon after the departure of the Romans and the arrival of the Saxons in 449, fashions of apparel were introduced from Northern Germany, which were copied by the Romanised British, and continued with no material change for several centuries.

The most important improvement in the ordinary dress of the people was the introduction of the *shirt*, a linen garment worn next the skin, for which we are indebted to the Saxon invaders. The common dress of the eighth century consisted, as we find, of linen shirts; tunics, or a kind of surcoat; cloaks fastened on the breast or shoulders with brooches; short drawers met by hose, over which were worn bands of cloth, linen, or leather, in diagonal crossings. Leathern sandals were worn by the early Anglo-Saxons; but afterwards the shoe became common: it was very simple, and well contrived for comfort, being opened down the instep, and there, by a thong passed through holes on each side of the slit, drawn tight round the feet like a purse. A felt or woollen cap, called *hæt* (hence our modern word hat), was worn by the higher class of Anglo-Saxons; but it is generally believed that the serfs or lower orders were without any other covering for the head than what nature had given them.

Although Sir Walter Scott, with the natural modesty of genius, disclaims pretension to complete accuracy in the costume of the characters in his historical romances, the following portrait of Gurth, the Saxon swineherd, in *Ivanhoe*, is nearly correct: 'His garment was of the simplest form imaginable, being a close jacket with sleeves, composed of the tanned skin of some animal, on which the hair had been originally left, but which had been worn off in so many places that it would have been difficult to distinguish from the patches that remained to what creature the fur had belonged. This primeval vestment reached from the throat to the knee, and served at once all the purposes of body-clothing. There was no wider opening at the collar than was necessary to admit the passage of the head, from which it may be inferred that it was put on by slipping it over the head and shoulders, in the manner of a modern shirt or ancient hauberk. Sandals, bound with thongs made of boar's hide, protected the feet; and a sort of roll of thin leather was bound artificially round the legs, and, ascending above the calf, left the knees bare, like those of a Scotch Highlander. To make the jacket sit more closely to the body, it was gathered at the middle by a broad leathern belt, secured by a brass buckle, to one side of which was attached a sort of scrip, and to the other a ram's horn, accoutered with a mouthpiece for the purpose of blowing. In the same belt was stuck one of those long, broad, sharp-pointed, and two-edged knives which were fabricated in the neighbourhood, and bore even at this early period the name of a Sheffield whittle. The man had no covering upon his head, which was only defended by his own thick hair matted and twisted together. One part of his dress only remains, but it is too remarkable to be suppressed: it was a brass ring resembling a dog's collar, but without any opening, and soldered fast round his neck; so loose as to form no impediment to his breathing, yet so tight as to be incapable of being removed, excepting by the use of the file. On this singular gorget was engraved, in Saxon characters—"Gurth, the son of Beowulf, is the born thrall of Cedric of Rotherwood."'

Anglo-Saxon Serf.

The Anglo-Saxon females wore under-tunics, with sleeves; another inner garment—the linen kirtle; and over these the long full gown, with loose sleeves. The head-dress was a hood or veil, which, falling down before, was wrapped round the neck and breast; and this was the only head-covering of the women when abroad. The hair was carefully dressed, and golden head-bands, half-circles, neck-bands, and bracelets were worn; with ear-rings, necklaces, crosses, and jewelled ornaments too numerous to describe. The hose and shoes resembled those worn by the men. The long sleeves of the gown or the mantle, drawn over the hands, served as gloves, which were not worn before the eleventh century. All classes used on their cheeks a red cosmetic, so that the art of painting the face is not the creature of refinement. The general colours of the dresses were red, blue, and green, sometimes embroidered in patterns; and gold tissue and cloth of gold were worn by princesses and nuns; and the latter embroidered robes, sandals, tunics, vests, cloaks, and veils of enormous cost—for pearls and precious jewels were interwrought with the materials, and sometimes three years were spent in working one garment; and their dresses were often lined

with sable, beaver, and fox furs, or the skins of lambs or cats.

In the article of dress, the Danish intruders into Britain were, after a time, equally profuse. The Anglo-Danish kings appear principally to have worn a red habit, embroidered with gold, and a purple robe; and their mantles were richly embroidered with gold and pearls. Upon a manuscript of the reign of Canute, he is, however, represented in a Saxon dress, the mantle being richly ornamented with cords or ribbons, and tassels; and he wears shoes and stockings with embroidered tops. His body, when discovered in Winchester Cathedral in the year 1766, was decorated with gold and silver bands, and a richly jewelled ring; bracelets were worn by all persons of rank, and invariably buried with them. Canute's queen wore the tunic, mantle, and long veil. The materials of the Danish dresses were cloths, silks, or velvets, procured either from Spain or the Mediterranean, by plundering the Moors.

From the Danish invasion to the Norman Conquest there were few changes in costume, if we except the imitation of Norman-French fashions in the reign of the Confessor, by shortening the tunics, clipping the hair, and shaving the beard, but leaving the upper-lip unshorn. Tattooing after the Pictish fashion was practised even to this time, although it had been forbidden by a law passed in the eighth century.

Eleventh till Fourteenth Century.

The Norman Conquest introduced a greater degree of taste and splendour into British costume; but the dress of the common order of people remained long of a comparatively rude fashion, partly from the effect of caste and sumptuary laws, which prevented any decided change. As time advanced, the materials of dress improved, but the fashioning was little different, and, till this day, we have a sample of the Anglo-Saxon tunic in the *smock-frock*, a species of overall linen shirt, very generally worn by the peasantry of England. The *blouse*, a coarse linen shirt of blue instead of white, which is now universally worn by workmen in France, Switzerland, the Low Countries, and part of Germany, had an equally early origin.

In the reign of Rufus many costly changes were made in dress: the tunics were lengthened, and the under garments even trailed upon the ground. The sleeves were also drawn over the whole hand, although gloves were worn, at least by the higher classes. The cloth mantles were lined with rich furs; and one lined with black sables and white spots cost £100. Extravagantly peaked-toed boots and shoes were worn; and a court coxcomb, who caused the points of his shoes to curl like a ram's horn, received the name of *De Cornibus*, or with the horns. The hair, which had been shorn from the back of the head as well as the face by the Norman-French, was now again worn long; and the courtiers in Stephen's reign even wore artificial hair, so that wigs may date from the twelfth century. The long beard also reappeared in the reign of Henry I. (1100–1135).

About this period, *gloves* highly ornamented appear to have been used by kings and the higher church dignitaries. Gloves, or a clothing of leather for the hands, had not been unknown in early ages; by the Greeks and Romans they were employed as a protection in certain kinds of rough labour. Now they were employed as part of a mailed dress, and also on ceremonial occasions. From the monumental effigy of Richard I., it is seen that he wore gloves ornamented with jewels on the back of the hand. Throwing down a glove became a challenge of defiance to single combat, according to the etiquette of these partially barbarous ages. From being worn only by kings, archbishops, courtiers, and knights, gloves made of various materials gradually became a portion of ordinary dress.

In the course of the thirteenth century, the sumptuousness of apparel increased: rich silks woven with gold, embroidered and fringed, and French velvets, were much used; and a rich stuff manufactured in the Cyclades was made into a dalmatica or super-tunic, called Cyclas, which was worn by both sexes. The furs of ermines, martens, squirrels, the vair, and the minevair or minever, were added to the list of furs for winter garments.

The general male dress consisted of the cyclas just mentioned, and the tunic; but the principal novelty is the super-totus, or overall, worn like the mantle or cloak, and consisting of a kind of large-sleeved shirt, with a capuchon. Long-toed shoes and boots were resumed, with embroidery and colours.

The female costume differed in fashion and name, rather than in form, from that of the twelfth century. The veils were of gold tissue or superbly embroidered silk, and over them was worn a diadem, circlet, or garland, or a caplike coronet, by persons of rank, and sometimes a round hat. The head-dresses were very numerous: the wimple covered the head and shoulders, and was fastened under the chin; and the hair was worn in a net or caul of gold-thread, which continued in fashion for the next two centuries. A very ugly kind of wimple, called the gorget, appeared in the thirteenth century; it was a neck-covering, poked up by pins above the ears. The long robe was also worn trailing on the ground; the cloth stockings were embroidered with gold; and trinkets of gold, as buckles, rings, earrings, and chaplets, and jewels, were much worn. In this century, too, we first meet with the surcol, which Strutt calls a corset, bodice, or stays, worn over the rest of the dress, which enlarged in the skirt, and spread into a train: it was made high in the neck, and had long tight sleeves.

The dress of the working-classes may be supposed to have been improved about this period by the introduction of the worsted manufacture: it is stated to have been brought to the country by a colony of Flemings, who in the reign of Henry II. settled at *Worsted*, a village in Norfolk; hence the name of the fabric.

Fourteenth and Fifteenth Centuries.

We now come to the fourteenth century, in which Edward III. and his queen Philippa led the fashion in apparel. As seen from the effigy on his tomb, the costume of Edward is characterised by its dignified simplicity. The dalmatica is low in the neck, falls in straight folds to the feet, and is open in front nearly half its height, being embroidered at the edges of the aperture; the sleeves of the under-tunic have at each wrist a row of buttons, a fashion of the reign of Edward III.; the mantle, embroidered at the edges, is worn over the shoulders, and confined by a jewelled band across the breast; the shoes or buskins are also embroidered, and the hair and beard are patriarchal; the crown has been removed or lost. The effigy of Queen Philippa, also at Westminster, is equally distinguished by its simplicity; the skirt is long and full, the bodice closely fitting, the waist-belt jewelled, and the mantle ornamented on the shoulders, and confined by a diagonal band across the breast; and upon the head is a low crown, jewelled, and from it depends a kind of draped ornament half-way down the cheek. The costume of the nobles in this reign was, however, far less simple than that of the sovereign. In place of the long robe and tunic was worn a close-fitting body-garment (jupon) superbly embroidered, reaching to the middle of the thigh, and confined across the hips by a splendid belt; from the sleeves of this garment hung long slips of cloth, called *tirippes* (tippets), and over the whole was occasionally worn a long mantle, fastened by buttons upon the right shoulder. This dress was, however, the extreme of foppery. The caps were of various shapes, and among them we find the knight's *chapeau*, nearly in the form now used in heraldry. Beaver hats were also worn; but the greatest novelty was a single feather in

the front of the cap. The golden chaplets, by the addition of leaves, now assumed the form of coronets. The gay tournaments of this period led to the introduction of many costly foreign fashions; so that, in 1363, expensive dress, beyond the income or rank of the wearer, was forbidden by law; furs of ermine and pearl ornaments (except for head-dress) were forbidden to all but the royal family and the wealthiest nobles; cloths of gold and silver were permitted only to the next in fortune; and persons of small income were forbidden to wear silks, embroidery, or trinkets. But the ladies dressed still more sumptuously, as in the engraving, where the gown fits close in the bodice, and the train is so long in the front as to be held up, and thus display the embroidered under-dress; the sleeveless jacket worn over the gown is also embroidered and trimmed with fur; the hair is worn long, and the cap is low, and resembles a coronet. Tippets from short sleeves, and the jupon, were also worn by ladies as well as by gentlemen; and both sexes wore daggers stuck through pouches in their rich girdles. In this reign *mourning habits* appear to have been first worn, the colours being black and brown.

Lady of Fourteenth Century.

The reign of Richard II. must have been the high carnival of coxcombry. The sovereign himself, according to Holinshed, had a coat or robe which cost 30,000 merks. Party-coloured dresses were universally worn; and even the hose were of two colours, so as to render the term a *pair* inapplicable: the colours of the king and his court were white and red. Men and women alike wore hoods set with jewels; and their tippets were jagged, and reached to the heels; and the long-peaked shoes, called *crackowes* (from Cracow, in Poland), were fastened to the knees with gold and silver chains. The preceding engraving shews a gentleman of this period, with shoes and hose all in one, the mantle cut into the shape of leaves at the edges, a belt and pouch, and a fantastically turbaned head-covering. Chaucer has left us the costume of several ranks at this period: his squire wears a short gown, 'with sleeves long and wide;' his yeoman, 'a cote and hoode of grene;' his merchant, many colours, with a forked beard, and a 'Flaundrish beaver hat,' and clasped boots; the reeve or steward, a long surcoat and rusty sword, his beard and head shaven and shorn; the miller wore a white coat and blue hood, a sword and buckler, and red-cloth holiday-hose; and the hats, caps, and bonnets of all classes were very fantastical. Knives, ornamented with silver, and purses, were worn by most classes in their girdles; and shoulder-belts, with bells, were a mark of rank. Liveries are also now mentioned as worn by substantial artisans, as well as by menial servants; but the ploughman appears only in a tabard or sleeveless coat, and the mechanic in a tunic. The hair was worn long and curled, and the beard forked.

Gentleman of Fourteenth Century.

In the female costume of this reign the fantastic party-coloured dresses were retained, with the embroidered jupons and kirtles, hip-kirtles, and long tippets from the elbow; and the surcol, or external corset, faced with fur, and terminating in a train sometimes so long as to be carried over the arm, or shorter, opened up the side, and bordered with ermine. The head-dress continued as in the preceding reign. The attire of the carpenter's wife in the *Canterbury Tales*, with a silk girdle and head-fillet and brooch, indicates the condition of this class of females.

The costume of the fifteenth century was equally gay and foppish, but perhaps more neat in form. The annexed engraving represents a gentleman of the reign of Henry V.: he is dressed in a short tunic, buttoned in front, with girdle, large loose sleeves, tight hose forming pantaloons, and stockings in a single piece, peaked shoes, and head-cloth or cap. About this period, silks and velvets of divers colours came into use among the higher classes, by whom gold chains were generally worn. The dress of ladies was of the richest kind. Gowns were embroidered and bordered with furs or velvet; and the bodice, laced in front over a stomacher, now first appeared. But the greatest eccentricity was the lofty steeple head-dress, shewn in the annexed portrait; this consisted of a roll of linen, covered with fine lawn, which hung to the ground, or was mostly tucked under the arm.

Gentleman of Fifteenth Century.

Richard III. (1483 - 1485), according to his wardrober's books, was a right royal fop; for we find him wearing a blue cloth-of-gold doublet and stomacher, 'wroght with netts and pyne-apples,' and crimson and purple-velvet robes, embroidered and furred, and crimson satin hose, and tissue cloth-of-gold shoes, at his coronation. The nobles in this reign had their hose tied by points to the doublet, which was sometimes worn open, but laced like a bodice; and over it was worn a long or short gown, the former hanging loose, and the latter plaited before and behind, and girded about the waist; and both gown and doublet were slashed. The general head-dress was a closely fitting cap or *bonet* (bonnet), with a single feather in it; and scarlet hats and hoods were worn. The boots had very long-pointed toes, and reached to the middle of the thigh.

Lady of Fifteenth Century.

Hitherto the authorities for costume have been illuminated manuscripts, tapestry, and monumental effigies, in which there is often perplexing indistinctness. Now, painting comes to our aid; and the portraits by Holbein are the best illustrations of the costume of the two succeeding reigns. The male costume of the wealthier classes in the reign of Henry VII. consisted of a fine shirt of long lawn, embroidered with silk round the collar and wristbands. The sleeves of the doublet were slashed at the elbow, as in the reign of Edward IV.; or they were in two or more pieces, fastened at the shoulders and elbows with laces or points, through which the shirt protruded. The doublet was laced over a stomacher and petticoat, the male costume thus resembling that of the females in name as well as form. The outer garment was a long coat or gown, with loose hanging sleeves, and a broad turn-over collar of velvet or fur. The long hose were

differently coloured in the upper and lower portions, and in the former slashed or puffed; the shoes were absurdly long and broad-toed, and high boots were worn for riding. In the head-coverings there was great variety. The hoods were abandoned to official habits, and instead were worn broad felt-hats or caps, and bonnets of velvet or fur profusely decked with ostrich feathers; or the large plumed cap was slung at the back, and a smaller cap of velvet or gold net worn on the head. The knave of our playing-cards has a cap peculiar to this period.

In these distracted times, party-colours were worn. Thus, the family colours of the House of Lancaster were white and red; those of York, purple and blue; and those of Tudor, white and green. Buttons also bore partisan figures or emblems.

The female costume of the reign of Henry VII. is distinguished by the square cut of the bodice in the neck, and embroidered and jewelled stomachers, belts, and girdles hanging in front nearly to the feet; the sleeves were large and full, and when confined at the wrist resembled 'the bishops' sleeves' imitated in England, from the French, a few years since. These sleeves were slashed, divided, and joined like those of the men. The head-dresses were close caps and cauls, from beneath which the hair hung down to the waist; and several kinds of capuchons were worn. In the dress of the humbler classes we find mentioned a 'furred flocket and gray russet rocket,' 'kirtle bristow red,' 'blanket hose,' 'Lincoln green,' &c.

At the close of this century the mourning habits had become so sumptuous as to be limited by law; the principal article being a barb or veil, used at funerals, which was tied on above the chin by duchesses and countesses, and lower by all other ranks.

Throughout the above period the principal material of the clothing of the middle classes must have been abundant; for, in the reign of Edward III., our woollen manufacture almost rivalled that of the Flemings, and our exports to the continent were very large; there appears, however, to have been little or no linen made at this period in England.

Sixteenth Century.

In the sixteenth century the upper part of the long hose began to be worn loose, or slashed with pieces of different colours let in, and the arms and shoulders of the doublet or jacket were fashioned in a similar style. Boots were also worn loose on the leg, with the upper part falling down; hence the origin of the *buskin*. Ruffs or ruffles, collars, and velvet bonnets with feathers, came likewise into use, as may be seen from the paintings of Henry VIII. Hall, the chronicler, describes several of Henry's superb dresses, and among them a *frocke*, or coat of velvet, embroidered all over with gold of damask, the sleeves and breast cut and lined with cloth of gold, and tied together 'with great buttons of diamonds, rubies, and orient pearls.' The cloaks and mantles were of corresponding magnificence. The shirts were pinched or plaited, and embroidered with gold, silver, or silk. The term *hose* continued to be applied to the entire vestment, from the waist to the feet, throughout this century: the material is more distinctly stated, for Henry wore knit silk as well as cloth hose; the precise period of the separation of the hose into breeches and stockings, is not so clear as the derivation of the latter term from the '*stockying* of hose;' 'that is, adding the lower part that covered the legs and feet to that which was fastened by points to the doublet,' and was called the *stocks*. The shoes and buskins were of the German fashion, very broad at the toes, and of velvet and satin, slashed and puffed. The hats, caps, and bonnets were of almost endless forms and colours.

Henry passed sumptuary laws, directing that cloth of gold and tissue should be used only for dukes and marquises, and that purple should be kept for the royal family. Earls might use embroidery, and commoners of distinction silks and velvets; and it was even thought necessary to restrict the commonalty and serving-men to cloth of a certain price, and lambs' fur, and to forbid them wearing any ornaments, or even buttons, save the badge of their lord or master. The king, likewise, forbade his courtiers wearing long hair, according to the general fashion, and made them poll their heads, which led to the introduction of the perûke, afterwards written *periwig*, and more shortly *wig*. The masques, or plays in masquerade, in Henry's reign, were very splendid; and in the ladies' dresses worn at one of them are mentioned 'demy sleeves, naked down from the elbows,' which M. Planché considers to have been the first appearance of bare arms since the time of the ancient Britons. Gloves were not unknown, for Henry left a pair to one of the executors of his will. They were sometimes finely perfumed, and brought from Spain and Italy as presents. In this and the preceding reign the head-dresses assumed a different character, having long lappets or ear-pieces hanging down below the shoulders, and when made of velvet studded with pearls, jewels, and gold, they were truly superb. Three-cornered caps of minever were also worn throughout the reign; and the close-fitting cap reaching to the ears, and known as 'Mary Queen of Scots' cap,' was first worn about this period. The ladies' hunting-dress differed but little from the riding-habit of the present day; across it was usually slung, from the right shoulder to the left side, a horn resembling a bugle.

In this reign, *pins* were first brought from France, and used by Catharine Howard, before which time the different parts of the dress were kept together by ribbons and loopholes, laces with points and tags, clasps, hooks-and-eyes, and skewers of brass, silver, and gold; but the poorer classes used the natural thorn for the above purpose.

The dress of the middle ranks in this reign may be seen in prints of the time; plain russet coats, and white kersey sloppes, or breeches, with stockings of the same piece, were the ordinary suit; and the London apprentices wore blue cloaks in summer, and gowns of the same colour in winter, as badges of servitude; for this appears to have been the age of domestic distinctions — the relics of the feudalism of the middle ages. The women wore sheep, russet, or long woollen gowns, worsted kirtles (hereafter called *petticoats*), and white caps and aprons; and milkwhite underlinen came into general wear. The engraving shews a man and woman in the ordinary dress of this period.

Man and Woman of the Sixteenth Century.

The principal novelty of the reigns of Edward VI. and Mary was the flat round bonnet or cap, of plain velvet or cloth, worn on one side of the head, and decorated with a jewel and single ostrich feather. The bonnet itself is preserved in the caps worn at the present day by the boys of Christ's Hospital; and their blue coat and yellow stockings are such as were worn by the London apprentices at the date of the foundation of the hospital by the youthful Edward. The gown of the wealthier classes was furred with sables in front and round the broad sleeves. Philip, on his marriage with Mary, brought into England a richer style of dress for the men, particularly the close ruff; the doublet, which fitted exactly under the chin, and the short Spanish cloak—all of which remained for a considerable time in fashion. The preposterously large stocks, or trunk-hose,

continued to be worn, but the broad-toed shoes were discarded. The armour continued nearly the same as in the preceding reign. To female costume the chief addition was the *fardingale*, an immense hooped petticoat, introduced from Spain under Queen Mary. The entire dress was worn very close, so as to conceal the person as much as possible.

Queen Elizabeth's fondness for dress is well known; she is stated to have left three thousand different habits in her wardrobe. This great number is explained by the royal affectation of wearing by turns the costume of all the nations of Europe, which may be traced to the use of foreign materials made up by foreigners. Bohun, in his character of Elizabeth, tells us that 'when she appeared in public she was richly adorned with the most valuable clothes, set off again with much gold and jewels of inestimable value; and on such occasions she even wore high shoes, that she might seem taller than indeed she was. The first day of the parliament she would appear in a robe embroidered with pearls, and upon her head she had a small crown. She was dressed in white silk, bordered with pearls of the size of beans, and over it a mantle of black silk, shot with silver threads. Her train was very long. Instead of a chain, she had an oblong collar of gold and jewels.'

But the glory of the Elizabethan era of female costume, as well as its most remarkable characteristic in the sixteenth century, was the *ruff* of plaited linen or cambric, which now became superb, and rose from the front of the shoulders behind the head nearly to its full height; from the bosom descended a huge stomacher, on each side of which projected the immense fardingale. In this characteristic costume Elizabeth went to St Paul's Cathedral to return thanks for the defeat of the Spanish Armada; though, besides the magnificent ruff, the queen wore a mantle with a large wing-like collar, her hair intertwined with pearls, large pendent jewels on the neck, and a superb lattice-work of pearls over the entire dress.

The ruff must, however, be further noticed: no sooner had its material been changed from Holland to lawn or cambric, than a difficulty arose as to starching or stiffening it, instead of the clumsy mode of supporting it by poking-sticks of ivory, wood, or gilt metal. At length the art of starching was brought from Flanders, and taught in London for a fee of four or five pounds. The fashion next lay in the colour of the starch, of which there were five varieties.

Stockings, which we find mentioned as foreign rarities in the wardrobe accounts of Henry VIII. and Edward VI., became common of home manufacture in the reign of Elizabeth. In the third year a pair of black knit silk stockings, made in England, was presented to her majesty, who was so pleased with the article, that she would never after wear cloth hose. This resolution has been attributed to Elizabeth's desire to encourage English manufactures by her own example, and may be taken as some set-off to her extreme fondness for foreign materials and fashions of dress. Soon after this, a city apprentice, having borrowed a pair of knit worsted stockings brought from Mantua, made a pair like them, which he presented to the Earl of Pembroke; and these are the first worsted stockings known to have been knit in England. Mary, queen of Scots, at her execution, wore stockings of blue worsted, clocked and topped with silver, and under them another pair of white; and the stockings of this time generally consisted of silk, jarnsey, worsted, crewel, fine yarn, thread, or cloth, of all colours, and with clocks, open seams, &c. The invention of the stocking-frame by Lee at Calverton, near Nottingham, in 1599, must have brought stockings into general use: he or his brother is said to have worked for Queen Elizabeth: but he was driven by the jealousy of the other stocking-manufacturers into France, where he died of a broken heart—an end by no means uncommon in the lives of inventors.

The garters of this age were very costly, sometimes of gold or silver, and £4 or £5 a pair; they are presumed to have been worn by ladies since the time of Edward II., but they must not be confounded with the leg-bandages of an earlier date. The ladies wore 'cocked shoes, prismets, pantoffles, or slippers,' which raised them two inches or more from the ground: these were made of black, white, green, or yellow velvet, or Spanish and English leather, embroidered with gold, silver, or silk, and shaped after the right and left foot, like the Anglo-Saxon sandal. The Elizabethan head-dresses were French hoods, hats, caps, kerchiefs, cauls of net-wire, and lattice caps—the latter, as well as an ermine bonnet, being forbidden by law to all but 'gentlewomen born, having arms.' In Elizabeth's jewel-box is a long list of wigs, or rather head-dresses, among which are cauls of hair set with seed-pearl and gold buttons. The hair was curled, frizzled, and crisped, and under-propped with pins and wires into the most fantastic forms. The finger-rings, earrings, bracelets, and other jewellery, were very splendid: velvet masks and pocket looking-glasses were carried by fashionables, with fans of ostrich feathers set in gold, silver, or ivory handles—the latter introduced from Italy, and used by both sexes.

The male costume in Elizabeth's reign was the large trunk hose, long-waisted doublet, short cloak, hat, band, and feather, shoes with roses, and the large ruff; but the great breeches, 'stuffed with hair like woolsacks,' after the separation of the hose into this garment and stockings, appear to have been worn throughout the reign: they were made of silk, velvet, satin, and damask. The doublets were still more costly, and quilted and stuffed, 'slashed, jagged, pinched, and laced;' and over these were worn coats and jerkins in as many varieties as there are days in the year. The cloaks were of the Spanish, French, and Dutch cuts, of cloth, silk, velvet, and taffeta of all colours, trimmed with gold, silver, and silk lace and glass bugles, inside and outside equally superb. The stockings, shoes, slippers, and ruffs resembled those of the ladies.

Hats now began to supersede the bonnets of a former era. Those of beaver were exceedingly expensive, and they were for the most part made of felted wool, dyed. The most remarkable thing about these hats was their numerous shapes: some were steeple-crowned; others were flat and broad, like the battlements of a house; and others with round crowns, and bands of all colours, and ornamented with huge feathers and brooches, clasps, and jewels of great value.

In taking leave of the British costume of the sixteenth century, we may observe that its splendour was almost entirely borrowed from France, 'that country which has since given laws in dress to nearly all Europe.'

Seventeenth Century.

Under James I. the male costume was somewhat more decidedly Spanish, as respects the slashing and ornamenting of the doublet and breeches. Late in the reign, however, the jackets or doublets were shortened, and the breeches reduced in size, and fastened in large bows at the knees; the well-stockinged leg was admired, and the hat worn low in the crown, and with broad brim, as seen in portraits of the date 1619. Beards and whiskers had become almost universal in the reign of Elizabeth; but in that of James, the former was sometimes worn trimmed to a point, hanging down at the division of the ruff.

In the female costume there was little change. The huge fardingale continued to be worn by the nobility; a strong passion for foreign lace was introduced; pearls were the favourite jewels; and the ruff maintained its sway, so as to be anathematised from the pulpit; and the fancies of female costume were glanced at in a sermon preached before the king at Whitehall in 1607–8, as 'her French, her Spanish, and her foolish fashions;

her plumes, her fannes, and a silken vizard, with a ruff like a sail, yea, a ruff like a *rainbow*, with a feather in her cap like a flag in her top, to tell which way the wind will blow.'

The dress worn in the reign of Charles I. is unrivalled for picturesqueness and elegant taste. At this we shall not be surprised, if we recollect that it was copied from the habit of Spain, the most becoming of all European costumes. Early in this reign, however, the motley fashion of the time of James I. prevailed; and the Savoy neck-chain, the ruff and cuffs of Flanders, the Naples hat with the Roman hat-band and Florentine agate, the Milan sword, and the cloak of Geneva set with Brabant buttons, gloves from Madrid, &c., were the characteristics of the beau of 1629. The ruff had almost universally given place to the falling band; and collars of rich point-lace, large and hanging down on the shoulders, held by a cord and tassel at the neck, and now called *Vandyke*, from its being the most striking part of the dress in which Vandyke at that time painted portraits.

The principal habits were vests and cloaks of velvet, or silk damask, short trousered breeches terminating in stuffed rolls, and fringes and points, and very rich boots, with large projecting lace tops. A dress of Charles is thus described:—A falling band, green doublet (from the armpits to the shoulders wide and loose), zigzag turned-up ruffles, long green breeches (like a Dutchman's), tied below the knee with yellow ribbons, red stockings, green shoe-roses, and a short red cloak lined with blue, with a star on the shoulder; the king sometimes wore a large cravat, and at other times a long falling band with tassels. The dress of the gay courtiers or cavaliers consisted of a doublet of velvet, silk, or satin, with large loose sleeves, slashed and embroidered; Vandyke collar and band, and short embroidered cloak, worn on one shoulder; the long breeches, fringed and pointed, met the ruffled tops of the boots; the embroidered sword-belt was worn over the right shoulder, and in it was hung a Spanish rapier; and in the flapping beaver hat was worn a plume of feathers confined by a jewel. A buff coat or jerkin was often worn, as a better defence than the doublet, which is sometimes covered. The engraving represents a citizen of this period more plainly attired.

Citizen in the time of Charles I.

The female costume of this period was rather elegant than splendid. Gowns with close bodies and tight sleeves were worn, though the fardingale was retained, with a gorget ruff standing up about the neck like a fan. French hoods were still worn, though with little distinction as to rank. The hair was worn in small curls, and the hoods, of all colours, fastened under the chin with curious effect. Earrings, necklaces, and bracelets were much worn; but the Puritans forbade the females to wear lace, jewels, or even braided hair; and they retained the close hood and high-crowned hat.

Towards the close of the reign of Charles I., the cumbrous fardingale disappeared, with the yellow starched ruff and band. These tasteless fashions having disappeared, the female dress became very elegant, with its rich full skirt and sleeves, and falling collar edged with rich lace, and the hair worn in graceful ringlets; but these vanities were condemned by the Puritan party.

With the Restoration of Charles II. came certain tasteless innovations upon the elegant Vandyke costume of the time of Charles I., which were the first resemblance to the coats and waistcoats of the present day. Thus our most picturesque attire lasted little more than a quarter of a century. Its decline was gradual; its chivalric character soon degenerated into grotesqueness, which in its turn changed to stark meanness. Early in the reign of Charles II., the doublet was much shortened, and worn open in front, where, and at the waistband, the rich shirt was shewn; and the loose sleeves and breeches were decked with ribbons and points, and from the knee-bands hung long lace ruffles. At the wrists, too, ruffles were worn; but the lace collar was shorn of its points, designated to this day Vandyke. The cloak was retained upon the left shoulder, and the high-crowned and plumed hat remained for a short time; but the crown of the hat was soon lowered.

The petticoat breeches were another absurdity; although ornamented with ribbons at the sides, the lining strangely appeared below the breeches, and was tied at the knees; to match which, the sleeves of the doublet only reached to the elbows, and from under them bulged the ruffled sleeves of the shirt, both being ornamented with ribbons. Meanwhile the skirt of the doublet had been lengthened from above the waist nearly to the knees, and had buttons and button-holes in its entire length, thus becoming a *coat*, and so named in an inventory of 1679; wherein also are the items of *waistcoat*, *breeches*, *pantaloons*, *drawers*, and *trousers*, being the earliest mention of these articles. Stockings of various kinds were common; and 'the lower ends of stockings' are understood as socks. Instead of the lace collar was worn the long square-ended cravat, of the same material, from Brussels and Flanders.

The female costume, as if to compensate for the tasteless additions to that of the men, retained much of its elegance in Charles's reign; indeed from this time 'the stronger sex' appear to have left the art of dress to the ladies. The portraits of the beauties of the court of Charles II., in Windsor Castle and Hampton Court Palace, are familiar illustrations, in which we see only a pearl necklace upon the bosom, and the hair falling in luxuriant ringlets from beneath a string of pearls. The gowns are of the richest satin, low in the bosom, and have long trains, so that the wearers could not 'stir to the next room without a page or two to hold them up.' The annexed engraving represents a citizen's wife performing this office herself.

Citizen's wife in the time of Charles II.

Passing to the reigns of James II. and William III., we find few noticeable novelties in costume. The coats were often of velvet, without collars, with large hanging sleeves, and button-holes of gold embroidery. The petticoat breeches were exchanged for the close-fitting garments tied below the knee, and therefore called *knee-breeches;* the broad-brimmed hats were turned up on two sides, and edged with feathers or ribbons; the fashion lay in the rich long lace cravat and embroidered waistcoat; the band was now narrowed, so as to resemble that worn at the present time by clergymen. The periwig was worn still longer than hitherto, hanging down in front, or flowing upon the shoulders, though the colour was altered from black to suit the complexion; and combing these wigs was a piece of gallantry, for which purpose a comb was carried, whence the origin of our present pocket-comb: and at court, in the walks of Kensington, the Mall of St James's, or the boxes of the theatre, the beaux turned their wig-curls over their

fingers whilst in conversation; the effect of these wigs flowing over the cuirass will be seen in the portrait of the great Duke of Marlborough.

The female costume was unchanged in the reign of James II.; but it became less luxuriant and more formal in the time of William and Mary, in accordance with Dutch taste. The waists were much lengthened with velvet stomachers, covered with jewels, so as to conceal the bosom, hitherto unsparingly exposed; the sleeve was made tight, and trimmed with lace lappets or ruffles, and long gloves were worn, so as entirely to cover the arm; but the skirts were worn long, full, and flounced; the hair, instead of flowing in ringlets, was gathered up, and strained over a toupee of silk or cotton wool, carried up so high as to be called a tower, covered with a lace scarf or veil that hung in front below the bosom; but this head-dress gradually shrunk into a caul with two lappets, known as a 'mob.' False locks and curls, set on wires to make them stand out, were also worn. Before the Revolution, the citizens' wives dressed with becoming plainness, and gentlewomen wore serge-gowns, which, after 1688, were rejected by chambermaids.

A few of the fashions and peculiarities of this century may be summed up in conclusion. From the reign of James I., the ladies appear to have dressed their hair in better taste than previously, in curls on each side of the face, and braided in a knot at the back of the head, where it was often ornamented with jewels or pearls, or a single feather. It was next worn in long locks flowing below the shoulders; and the love-lock, ornamented with ribbon and twisted pearls, was worn on one side. From the reign of Charles II. to that of Queen Anne, long hair was much prized, and was often sold by women of inferior fortune to be made into periwigs. About this time the *fontange*, or top-knot, so called from Mademoiselle de Fontange, who first wore it, was driven out of fashion by the fanatical spirit of the time. *Hair-powder* was also introduced from France in this century: it was worn of various colours—an absurdity only discontinued at the close of the last century. Towards the close of the century, wigs became fashionable, together with false hair—'a custom contrary to our forefathers, who wore their own hair.'

Under the House of Stuart, the shoe-rose yielded to the shoe-string, the beaux wearing them of silk tagged with silver, and the humbler classes wore laces of plain silk, or even leather thongs—the latter still to be met with in rural life. Shoe-buckles, in size and shape resembling the horse bean, were introduced at the period of the Revolution.

Eighteenth Century.

In the early part of the eighteenth century, the costume of the English gentry was greatly affected by that introduced into general usage in France by Louis XIV. About the reign of Queen Anne, the new French fashions had been embraced by courtiers, physicians, and other professional persons in England, also the higher order of gentry; and in the following reigns of George I. and II., they became universal.

This dress of the old English gentleman, as it afterwards came to be called, consisted at first, during Queen Anne's reign, of a periwig in formal curls, partly contained in a silk bag on the shoulder; a small cocked-hat, full-bottomed coat, short breeches, blue or scarlet stockings drawn over the knee, and square-toed shoes, with small buckles and high red heels. And this formal costume, relieved only by lace cuffs, ruffles, and neckcloth, and gold or silver clocks in the stockings, remained unmodified through three-quarters of the century. The engraving shews a gentleman of the year 1750, and reminds us that the snuff-box, first carried in the reign of James II., continued indispensable for the 'fine gentleman.' The origin of the cocked-hat is easily explained. The wide flaps or broad brims of the hats in use being found to be inconvenient, they were looped up with a cord and button. At first this was done according to fancy, but latterly there were distinct fashions in cocking the hats. Cocked-hats, richly trimmed with gold-lace and ostrich feathers, occur in Hogarth's pictures, which indeed will furnish a better idea of the entire costume from 1727 to 1760 than many pages of description; and the portraits of Sir Joshua Reynolds will supply the dress of the next forty years.

Gentleman of 1750.

The fashions of wigs were as various as those of hats. A peruke and a plaited and tied tail were called a Ramillies, from the famous battle of that name. The tie-wig became the fashion, from the celebrated Lord Bolingbroke going to court with his wig tied up, upon which Queen Mary observed that he would 'soon come to court in his night-cap'—a royal rebuke which established a fashion. In 1764, wigs went out of wear, and the wig-makers of London petitioned George III. to compel gentlemen to wear wigs by law, for the benefit of their trade! In the present day, formal wigs are almost confined to the heads of prelates and law-officers; and the latter, to get rid of the powder nuisance, wear wigs made of other materials than hair—as the metal platina. Wigs are, however, much worn, from the greater prevalence of baldness than formerly; but their perfection now consists in bearing so close a resemblance to the natural or living hair as to avoid detection.

Towards the middle of the reign of George III., the male dress took the form of the court suit worn at the present day; the breeches having, from the year 1760, been worn over the knees, fastened by buckles or strings. The coats of the eighteenth century were of velvet, silk, or satin, as well as broadcloth, and their colours very fanciful. Hogarth's favourite colour was sky-blue; Reynolds's, deep crimson and violet; and Goldsmith rejoiced in plum-colour. About 1790, cloth became the general wear; the waistcoat being of the costlier materials, and embroidered, and sometimes the breeches. Buckles were worn at the knees and in the shoes till the close of the last century; and the large square plaited buckle was the *ton* until 1791, when shoe-strings became general; though the Prince of Wales and his household endeavoured, by wearing buckles, to retain the fashion.

The female costume of the eighteenth century was as formal and tasteless as that of the men. The most odious piece of attire introduced in the early part of the century was the large whalebone petticoat, which degenerated into the hooped petticoat, and made a lady to appear as if standing in an inverted tub. In the reigns of George I. and II., loose gowns, called *sacques*, and hooded silk cloaks, were worn, and a very small muff, such as have been lately revived. This costume is shewn in the above portrait of a lady of George II.'s time. Ornamental aprons were also worn, as at the present day, with the watch, necklace, and the fan, which was sometimes from

Lady in the time of George II.

twelve to eighteen inches in length, and beautifully made. Gay sings—

> The fan shall flutter in all female hands,
> And various fashions learn from various lands.
> For this shall elephants their ivory shed,
> And polished sticks the waving engines spread:
> His clouded mail the tortoise shall resign,
> And round the rivet pearly circles shine.
> On this shall Indians all their art employ,
> And with bright colours stain the gaudy toy:
> Their pains shall here in wildest fancies flow;
> Their dress, their customs, their religion shew..

Spanish broadcloth, trimmed with gold-lace, was used for ladies' dresses in the reign of George I.; and furbelowed scarfs were worn from the duchess to the peasant.

Veils of the finest material, as a shroud to the female features, are of great antiquity, and may be traced to Oriental nations, among whom the seclusion of women from general gaze is a point of etiquette. In the eighteenth century, in England, after the disuse of towering head-dresses, veils of an elegant fabric were introduced, and still are not altogether out of date. Female caps of gauze or muslin are of French origin, and have always been multifarious in form. The bonnet, in early times generally made of velvet, cloth, and silk, was in the eighteenth century changed to straw. Gay mentions a new straw-hat lined with green, about 1724, but it was then comparatively rare; for the simple art of plaiting straws together to make bonnets was only practised to any considerable extent about sixty years since.

Nineteenth Century.

The formalities of the eighteenth century received a terrible blow at the French Revolution; and in the ten years from 1790 to 1800 a more complete change was effected in dress, by the spontaneous action of the people, than had taken place at any previous period in a century. The change began in France, partly to mark a contempt for old court usages, and partly in imitation of certain classes of persons in England, whose costume the French mistook for that of the nation generally. This new French dress was introduced by the party who were styled the Sans Culottes. It consisted of a round hat, a short coat, a light waistcoat, and pantaloons; a handkerchief was tied loosely round the neck, with the ends long and hanging down, and shewing the shirt collar above; the hair was cut short, without powder, *à la Titus*, and the shoes were tied with strings.

The comparatively simple form of dress of the Sans Culottes found many admirers in England, and soon became common among young men; the change from antique fashions was also greatly helped by the imposition of a tax on the use of hair-powder, which was henceforth generally abandoned. Pantaloons, which fitted closely to the leg, remained in very common use by those persons who had adopted them till about the year 1814, when the wearing of trousers, already introduced into the army, became fashionable. It is proper, however, to mention that trousers had, for the previous fifteen or twenty years, been used by boys, and were perhaps from them adopted by the army. Previous to the French Revolution, the dress of boys was almost the same as that of men. Although trousers were generally worn after 1815, many elderly persons still held out in knee-breeches against all innovations, and till the present day an aged gentleman may occasionally be seen clinging to this eighteenth-century piece of dress. The general use of white neckcloths continued, notwithstanding the introduction of the standing collar, till the reign of George IV., when this monarch's taste for wearing a black silk kerchief or stock, and also the use of black stocks in the army, caused a remarkably quick abandonment of white neckcloths, and the adoption of black instead. The year 1825, or thereabouts, was the era of this signal improvement in costume.

While these leading changes were effecting, other alterations of a less conspicuous nature were from time to time taking place. The disbanding of the army after the peace of 1815 led to various transformations besides those we have mentioned. While pantaloons were the fashionable dress, it became customary to wear Hessian boots; these, which had originated among the Hessian troops, were without tops, and were worn with small silk tassels dangling from a cut in front; being drawn over the lower part of the pantaloons, they had a neat appearance; but the keeping of them clean formed a torment that prevented their universal use. When trousers were introduced from the practice of the army, the use of Wellington boots to go beneath them also became common.

Referring to the era of 1815 to 1825 as that in which trousers, Wellington boots, and black neckcloths or stocks came into vogue, we may place the introduction of the surtout in the same period of history. From the time when the collarless and broad-skirted coat had disappeared about the commencement of the century, the fashion of coats had changed in various ways till the above-named era, when the loose frock-coat or surtout was added to the list of garments. We remember seeing French military officers, when in undress, wearing frock-coats as early as 1811; it is probable, therefore, that the modern surtout is only a variety of the loose military great-coat brought from the continent by the British army; however it originated, it may be allowed to be one of the greatest improvements in the style of dress which has yet occurred in the nineteenth century.

On the whole, the dress of the current age is characterised by simplicity and elegance. The male attire is plain, and in good taste, with the exception of the 'dress-coat' and hat, both of which are as unnatural in cut as they are void of comfort. Female attire was never perhaps more chaste and becoming; the chief article which occasionally merits censure being the ever-changing but never very classic-looking bonnet. And yet, though convinced of an occasional absurdity in the matter of costume, it is the wiser course rather in so far to follow than attempt to lead in an altogether different direction. 'A man,' says Feltham, and he says wisely, 'ought, in his clothes, to conform something to those that he converses with, to the custom of the nation, and the fashion that is decent and general, to the occasion and to his own condition; for that is best that best suits with one's calling and the rank we live in. And seeing that all men are not Œdipuses, to read the riddle of another man's inside, and that most men judge by appearances, it behoves a man to barter for a good esteem, even from his clothes and outside. We guess the goodness of the pasture by the mantle we see it wears.'

PROVINCIAL PECULIARITIES.

The *Welsh*, as a relic of an ancient Celtic people, possess remarkably few external traits of their original. They have, like the Irish, become Anglicised in costume, and we should in vain search amongst them for the *breacan*, or checkered clothing, of their Celtic ancestry. The most remarkable part of the Welsh costume is the hat worn by the women. All females in parts of the country not modernised wear round black hats, like those of men; and this fashion is supported to a small extent by ladies of the higher rank. This use of the hat is not Celtic; the fashion is derived from England, and is only two or three centuries old.

The *Irish* at an early period wore the same Celtic fashion of attire as was preserved till recent times in the Scottish Highlands; but, as in Wales, everything of the kind disappeared as the country became Anglicised. A primitive species of attire, including coloured mantles, kirtles, and other fanciful garments, remained in use

till the sixteenth century, when laws were passed by Henry VIII., enjoining the use of caps, cloaks, coats, doublets, and hose of English cut, but of Irish or any other materials. The general dress in Ireland, at the present day, rarely varies from that in England. There are, however, some interesting peculiarities of costume amongst the peasantry of the southern and western counties.

The costume of the Lowland Scotch has generally resembled that of the English in all its changes and vicissitudes. At the present day, Scotland cannot be said to possess any national costume which distinguishes the bulk of the people from their fellow-subjects in South Britain; and however much the fact may surprise the artists and dramatists of England, it is very certain that the inhabitants of Edinburgh, Glasgow, and other cities and towns of Scotland, are dressed in precisely the same fashion of garments as is now seen in the streets of London, Paris, Brussels, or the capital of any other civilised country.

Anciently, the dress of the Scotch, both those of the Highlands and Lowlands, was distinguished by party-colours, woven in checks, according to taste or ancient usage. By the Celtic race in the Highlands, this species of variegating cloth with colours was called *Breacan*, which signifies spotted; and by the Teutonic population of the Lowlands it received the name of *Tartan*, a word whose origin has defied the researches of etymologists, but which it is not unlikely may have been derived from the ancient Tatar races, who used a similar kind of colouring in their attire. Till the present day, cloths checked in various colours are worn by the Calmucs and other tribes in the north of Europe. Tartan for clothing disappeared in the Lowlands of Scotland in the course of the seventeenth century; but even as late as the beginning of the eighteenth century, party-coloured plaids were pretty generally worn; and young women were in the habit of using a 'tartan screen'—that is, a small plaid of variegated colours. The tartan screen, which was worn in the fashion of a covering for the head and shoulders, so as to combine in some measure the properties of a modern bonnet and shawl, was formed of costly materials; the ladies of the higher classes employing silk, and those of inferior station fine worsted, the colours in each case being remarkably brilliant. Being often employed with a degree of real or affected modesty to conceal a part of the features, it may be said to have performed the office of a veil to Scottish maidens; and hence its appellation of *screen*. Perhaps the use of this species of coif was a consequence of a point of etiquette, which rendered it indecorous for young unmarried women to wear any regular garment on the head.

While tartan disappeared from the Lowlands, except in the screens of the women and the plaids of the shepherds, it continued to be in universal use in the Highlands, where it may be said to have been always associated with the manners of the people; and this leads us to say a few words respecting

Highland Costume.—Originally, the costume of the Highlanders resembled that of other Celtic tribes, and consisted of little else than a woollen garment of variegated colours, wrapped round the body and loins, with a portion hanging down to cover the upper part of the legs. In progress of time this rude fashion was superseded by a distinct piece of cloth forming a philibeg or kilt, while another piece was thrown loosely as a mantle or plaid over the body and shoulders. In either case, the cloth was variegated in conformity with the prescribed *breacan*, or symbol of the clan; and hence the tartan was sometimes called *cath-dath*, or battle-colours, in token of forming a distinction of clans in the field of battle.

According to the author of the *Vestiarium Scoticum*, the following, in the reign of James VI., was the list of chief and subordinate clans, each possessing its own tartan; among these clans, it will be observed, are included certain Lowland families or houses, who had also adopted the same kind of cognizance:—

Clan Stewart—six colours, chiefly red, checked with green, purple, black, white, and yellow.
Prince of Rothsay—three colours, checked with green and white.
Royal Stewart—chiefly white, checked with green, red, purple, and black.
Macdonald of the Isles—chiefly green, checked with black, purple, red, and white.
Ranald—chiefly green, checked with black, purple, red, and white.
Macgregor—chiefly red, checked with green and white.
Ross—chiefly red, checked with green and purple.
Macduff—chiefly red, checked with green, black, and purple.
Macpherson—equal portions of black and white, with small lines of red and yellow.
Grant—chiefly red, with checks of green and purple.
Monro—chiefly red, checked with black and white.
Macleod—chiefly yellow, checked with black and red.
Campbell—chiefly green, checked with black, purple, yellow, and white.
Sutherland—chiefly green, with black, purple, red, and white.
Cameron—chiefly red, checked with green and yellow.
Macneil—chiefly green, with purple, black, white, and red.
Macfarlane—very dark, being chiefly black, checked with white.
Maclachlan—chiefly yellow, with checks of brown.
Gillean or Maclean—chiefly green, checked with black and white.
Mackenzie—nearly equal portions of green and purple, checked with black, white, and red.
Fraser—chiefly red, checked with purple, green, and white.
Menzies—equal portions of red and white.
Chisholm—chiefly red, checked with purple, green, and white.
Buchanan—chiefly red and white, with small black stripes.
Lamont—chiefly green, checked with black, purple, and white.
Macdougall—chiefly red, checked with black, purple, and green.
Mackintyre—chiefly green, checked with purple, red, and white.
Robertson—chiefly red, checked with purple and green.
Macnab—chiefly red, checked with crimson, green, and black.
Mackinnon—chiefly red, checked with green, black, and white.
Mackintosh—chiefly red, checked with green, black, and white.
Farquharson—chiefly green, with purple, black, red, and yellow.
Gun—chiefly green, checked with black and red.
Macarthur—chiefly green, checked with black and yellow.
Mackay—chiefly a bluish purple, with black and red checks.
Macqueen—nearly equal portions of red and black, with yellow.
Bruce—chiefly red, with green, yellow, and white.
Douglas—very dark, being equal checks of black and slate colour.
Crawford—equal portions of red and green, with white.
Ruthven—chiefly red, with purple and green.
Montgomery—chiefly light green, checked with purple.
Hamilton—chiefly red, with purple and white.
Wemyss—chiefly red, checked with black, white, and green.
Comyn—chiefly red, with green, black, and white.
Sinclair—chiefly green, checked with black, purple, red, and white.
Dunbar—chiefly red, checked with green and black.
Leslie—chiefly red, checked with purple, black, and yellow.
Lauder—chiefly green, with purple, black, and red.
Cunningham—chiefly red, with black, purple, and white.
Lindsay—chiefly red, with purple and green.
Hay—chiefly red, with green, yellow, white, and black.
Dundas—chiefly green, with purple, black, and red.
Ogilvie—chiefly green, beautifully checked with purple, black, yellow, and red.
Oliphant—equal portions of green and purple, with black and white.
Seton—chiefly red, with small lines of green, black, purple, and white.
Ramsay—chiefly red, with black squares checked with white.
Erskine—red and green.
Wallace—red and black, checked with yellow.

Brodie—chiefly red, with black and yellow.
Barclay—chiefly light green and purple, checked with red.
Murray—chiefly green, checked with black, purple, and red.
Urquhart—chiefly green, with black, purple, white, and red.
Rose—chiefly red, with small checks of purple, green, and white.
Colquhoun—green, purple, black, red, and white.
Drummond—chiefly red, with green and dark red.
Forbes—chiefly green, with black, red, and yellow.
Scott—chiefly red, with green, red, and black.
Armstrong—chiefly green, with black, purple, and red.
Gordon—chiefly green, with purple, black, and yellow.
Cranstoun—yellowish green, with purple and red.
Graham—chiefly green, with black checks.
Maxwell—chiefly red, with green and black.
Home—dark purple, with black, red, and green.
Johnston—chiefly green, with purple, black, and yellow.
Ker—chiefly red, with black and green.

In 1747, with the view of breaking the spirit of the clans, a law was enacted proscribing the use of the Highland dress, including the tartan in all its varieties. The following is the provision in the act of parliament on the subject:—'That from and after the 1st day of August 1747, no man nor boy, within that part of Great Britain called Scotland, other than such as shall be employed as officers and soldiers in his majesty's forces, shall, on any pretence whatever, wear or put on the clothes commonly called Highland clothes—that is to say, the plaid, philibeg or little kilt, trowse, shoulder-belts, or any part whatsoever of what peculiarly belongs to the Highland garb; and that no tartan or party-coloured plaid or stuff shall be used for great-coats or for upper-coats; every person offending, being convicted by the oath of one or more credible witnesses before any court of justiciary, "shall suffer imprisonment, without bail, during the space of six months;" and being convicted for a second offence, shall be transported to any of his majesty's plantations beyond seas, there to remain the space of seven years.' This contemptible law was repealed in the year 1782; but before that time the tartan and the 'garb of old Gaul' had been generally abandoned, except among Highland regiments, and it is chiefly copies from their attire that have guided modern attempts at reviving the costume.

As modernised and improved by the Highland regiments, the 'belted plaid,' worn as the philibeg or small kilt, with a separate drapery depending from the shoulder in imitation of the ancient garb, is one of the most picturesque and graceful costumes to be seen in any part of the world; and although it leaves the legs bare at and a short way above the knee, we are assured that it is by no means too meagre an attire for cold weather. Anciently, the Gael wore no shoes or garments for the legs. The feet were only on occasions covered with pieces of hide, tied with a thong, called *brogs*, which, though slender, were very lasting, and were well suited for walking or running on heathy mountains. The introduction of shoes, and also hose, formed from the same tartan cloth as the kilt, is comparatively modern. The hose of the common men in the Highland regiments are still not knitted or woven like stockings, but cut from the web and sewed. It appears that even in ancient times the Celtic tribes did not always wear the loose garments we have described; but that they also, or at least some of them, wore the *triughas* or *trius*, a species of vestment 'formed of tartan cloth, nicely fitted to the shape, and fringed down the leg.'

The coat, in which the upper part of the body and arms of the Highlanders are now invested, is of course quite modern, having come into use when the old form of the plaid dress was laid aside. Made, as it usually is, with short skirts and small round buttons, it cannot be considered in harmony with the rest of the attire; but it is nevertheless convenient.

The bonnet has for ages been a part of the Highland costume, as it was formerly also of the Lowlanders, and of the English, previous to the introduction of felt hats. The English gave up bonnets sooner than the Scotch; and ultimately the cry that 'the blue bonnets had come over the Border,' was equivalent to saying that a party of Scotch marauders had entered England on one of their usual hostile excursions. The Highlanders, with whom the bonnet has remained longest as a part of ordinary

Highlander.

dress, have adopted very many shapes and modes of ornamenting their headgear. The heavy plume of black feathers used in the army is quite modern, and in exceedingly bad taste, besides being totally unconformable to the idea of a primitive and light costume. The true bonnet of the Highlands is small, either round or peaked in front, dark-blue or gray in colour, and without any tartan or checkering. In fancy dress, however, the bonnet is somewhat larger, and occasionally has a band of tartan. Highland chiefs were distinguished by three pinion feathers of the native eagle stuck in the bonnet; and those who enjoyed the rank of gentlemen were entitled to wear a single feather. It was customary also for the members of each clan to wear in the bonnet a peculiar badge formed of some native shrub. Authorities differ as to the precise shrubs worn for this purpose. The Buchanans used a sprig of bilberry; the Camerons, crowberry; the Campbells, fir-club-moss; the Forbeses, broom; Frasers, yew; &c.

The full dress of Highland chiefs and gentlemen has always been liberally ornamented with sword, baldrick, dirk, skean-dhu (worn in the stocking) large brooches, buckles, shot-pouch, and purse. The purse or sporan is a most important part of the costume; it is formed of the skin of a wild animal with the hair on, and tied to the waist by a band, hangs down in front, so as to fall easily upon the lap, and not incommode the legs in walking. It is usually ornamented with silver tags and tassels, and a flap covering the mouth of the purse is sometimes decorated with the vizard of a fox.

After a period of indifference to the preservation of the Highland dress, a revival of the national tone of feeling respecting it has been for some time apparent. At the same time, it is employed only as a fancy costume on festive or gala occasions; and in the Highlands, the ordinary dress of the English is in common use.

INDEX, AND GLOSSARY OF TERMS.
